To Arvid Wallgren

Preface

The six papers[1] in this supplement are the first collected results of a longitudinal study of the biological growth of children, somatic as well as mental development.

The study is part of an international coordinated investigation organized by the Centre International de l'Enfance in Paris. The Swedish study was started in 1954 at the Paediatric Clinic, Karolinska sjukhuset, where it is still in progress.

Professor Arvid Wallgren was the initiator of the Swedish study and has since the start inspired and encouraged the members of the Growth team and supported them in every way. After Professor Wallgren's retirement the team has been able to continue the study with the support and assistance of Professor John Lind.

The study was financially facilitated by grants from
Centre International de l'Enfance
Swedish Medical Research Council

children of different ages, in a variable such as height or intelligence scores will throw no light on the course of growth in individual children It is highly misleading to think in terms of the height of the average child at each age and connecting these points, to assume that this mythical child could grow in this way The average not only conceals irregularities of growth rates in individual children, but may also conceal or greatly distort common trends such as the adolescent spurt when these occur at different ages in different children

In the United States the great value of longitudinal investigations was recognized at an early stage among others by Bayley [2] Dearborn & Rothney [7] Jones [18] MacFarlane [24] Shuttleworth [42] Sontag [44] Stuart [56 57] and Washburn [60]

The present investigation forms a link in international studies on the development of children co-ordinated by the International Children s Centre (I C C.) in Paris Those studies, listed in the order in which they were started are in progress in London, Paris Zürich and Brussels in Europe, in Dakar and Kampala in Africa and in Louisville in the United States An account of this internationally co-ordinated study with regard to its aims design and methods has been given in volume V of Modern Problems in Pediatrics with Frank Falkner as co-ordinator and editor and with contributions from team members in the different centres [13]

The general aim of these studies has been formulated as follows [16]

Within each country

(i) To chart the course of physical and psychological development of children, in terms of a number of important variables. (ii) To obtain reasonably comprehensive life histories, which will be applicable to a considerable variety of problems. (iii) To employ a sufficiently large sample to permit of statistical analysis (iv) To relate important features of development to other important variables, as, for example social background size of family parental methods, health etc (v) To study the inter relationship of one feature of development with another as, for example of physique and health behaviour problems and previous experience intelligence and physical health or of physique and behaviour

Between countries

(i) To determine to what extent the developmental process, and inter relationships between variables, show similar or different features in different countries. (ii) Where clear differences exist to attempt to explore the possible reason for them.

Owing to the intimate interrelationship between physical and psychological factors an adequate study of growth and development must include coordinated examinations and observations by various specialists A broad approach is essential. By repeated physical examinations and various body measurements and through simultaneous comprehensive psychological interviews and tests, as well as by an appraisal of social environment a picture of the total child in its environment may be attained An impairment of a child s physical health readily affects his general behaviour and conversely mental stress may cause marked changes in bodily functions

The aim of the Swedish investigation is to study children in a Swedish urban community in the Stockholm region according to the above mentioned principles Our primary main objects are

The physical investigations should be so designed as to give a broader picture of the growth of normal children than is available at present in Sweden. This can be achieved owing to the increased number of body measurements that are taken and to the longitudinal approach adopted for the evaluation of the growth process as such. Special emphasis is focused on increments for various age periods. Our purpose is to develop also a more detailed method of evaluating skeletal maturation from a smaller number of X-ray examinations than are made at present in Sweden.

The primary aim of the psychological investigations is the elucidation of those point which physicians teachers psychologists, parents and other persons who have to deal with children every day are compelled to take into consideration. There re for example the variation in sleep sleep disorders and sleep requirement time for cleanliness and toilet training eating habits and eating problems jealousy of siblings, different forms of fears et Our knowledge is very limited with regard to the variation in children behaviour att tudes and emotional reactions. Furthermore in the psychological investigations we endeavour to get a picture of emotional and int llectual maturation and the development of the child personality i his interaction with the other members of his f mily In connection with this are interested in studying the identification process and the child s adaptation to society and its value norms. In Sweden, however there is a shortage of standardized and well validated personality tests, especially for mall children. Experience gained with a battery of such techniques will increase the possibilities of evaluating personality development in children.

It is hoped that the present investigation may contribute to the discussion on the distribution of the intellectual, testable ability levels in different social groups. By testing children from infancy up through the years when the influence of the cultural environment probably becomes stronger the investigation may furnish information regarding possible shifts in the level of ability

This study may also assist in elucidating whether it is possible to predict at an early stage a child s vulnerability In the first place, we have in mind those children who are highly sensitive

We may summarize by stating that the main purpose of this investigation is to widen the knowledge on which preventive child care and the clinical judgement of children are based, and to attain a more profound and detailed insight into the mechanisms that guide the growth and development of children.

The organization of the Swedish study The Swedish study initiated by Arvid Wallgren, began to be planned in the autumn of 1954 after two of us (P K. and G K.) had had the opportunity of attending the first Annual Growth Meeting of the I C C. in Paris. At this meeting all the study groups were represented that were then participating A team was formed with two other members (L. K. L. and H L.), and during the winter of 1954–55 the studies were planned and modelled mainly on the pattern of the London study Much work was expended on elaborating and standardizing the forms, especially the interview forms, and on arranging the forms so that they could be

children of different ages, in a variable such as height or intelligence scores will throw no light on the course of growth in individual children. It is highly misleading to think in terms of the height of the average child at each age and connecting these points, to assume that this mythical child could grow in this way. The average not only conceals irregularities of growth rates in individual children but may also conceal or greatly distort common trends such as the adolescent spurt when these occur at different ages in different children.

In the United States the great value of longitudinal investigations was recognized at an early stage among others by Bayley [2] Dearborn & Rothney [7] Jones [18] MacFarlane [24] Shuttleworth [42] Sontag [44] Stuart [56 57] and Washburn [60]

The present investigation forms a link in international studies on the development of children co-ordinated by the International Children's Centre (I C C) in Paris. These studies, listed in the order in which they were started are in progress in London Paris, Zürich and Brussels in Europe, in Dakar and Kampala in Africa and in Louisville in the United States. An account of this internationally co-ordinated study with regard to its aims, design and methods has been given in volume V of Modern Problems in Pediatrics with Frank Falkner as co-ordinator and editor and with contributions from team members in the different centres [13]

The general aim of these studies has been formulated as follows [16]

Within each country

(i) To chart the course of physical and psychological development of children in terms of a number of important variables. (ii) To obtain reasonably comprehensive life histories, which will be applicable to a considerable variety of problems. (iii) To employ a sufficiently large sample to permit of statistical analysis. (iv) To relate important features of development to other important variables, as, for example social background size of family parental methods, health etc. (v) To study the inter relationship of one feature of development with another as, for example of physique and health, behaviour problems and previous experience intelligence and physical health or of physique and behaviour

Between countries

(i) To determine to what extent the developmental process, and inter relationships between variables, show similar or different features in different countries (ii) Where clear differences exist to attempt to explore the possible reasons for them

Owing to the intimate interrelationship between physical and psychological factors an adequate study of growth and development must include coordinated examinations and observations by various specialists. A broad approach is essential. By repeated physical examinations and various body measurements and through simultaneous comprehensive psychological interviews and tests as well as by an appraisal of social environment a picture *of the total child in its environment* may be attained. An impairment of a child's physical health readily affects his general behaviour and conversely mental stress may cause marked changes in bodily functions

The aim of the Swedish investigation is *to study children in a Swedish urban community in the Stockholm region according to the above mentioned principles. Our* primary main objects are

child is examined at the clinic at the following ages, 1 month (4 weeks), 3 months (13 weeks), 6 months (26 weeks), 9 months (39 weeks), 1 months, 18 months, years and thereafter once a year. In order that the investigations may be considered to represent actual ages, the following tolerances as regards time are permitted for the age of 4 weeks ± * days, for 3–18 months ± 1 week, for *-3 years ± weeks and subsequently − weeks and + 4 weeks.

At each visit the following examinations and observations are made.

Somatic history is recorded including a general appraisal of health since the last visit and a cl ical examination is performed with a general appraisal of the present condition of health at tus.

Body measurements are taken for 16 different parts of the body area (Fig. 1) including measurements of the kinfolds at four different places.

Roentgenological exam nations of a wrist, ankle and knee are carried out in order to estimat the skeletal development judged by the size and shape of the ossification centers. In addition the calf is also examined to determine the thickness of the soft tissue.

Photographs of the child in different positions are taken. From the f 4 years these re carefully standardized in order to enable sessment of body constitution (Fig. 1).

Psychological interview with special reference to the child functional development and beha iour. They comprise set of detailed question in accordance with standard form nd last about one and half hours. They are focused on different habits and traits as well a on the parents method of handling the child.

Fig. 1. The various body measurements taken.

Up to 3 years these interviews take place only with the mother but when the child is 4 years old the father as well is interviewed (at home). Both parents fill in an ttitude scale (abridged Schaefer Bell) [41]. We also ask them about their attitudes to their own upbringing.

Psychological testing. Starting from the age of 3 months and continuing up to years a psycho-motoric development test for infants (Brunet Lézine [4], a modification of the Gesell test) is used. This test i applied also in the majority of the other centres. At the age of 3 years the intelligence level is assessed by the Terman Mer

used later for punch-card analysis Meetings arranged by the I C C 1954 Paris 1955 Stockholm 1956 London, 1958 Brussels 1960 Zürich 1962 London [6] and personal contacts have facilitated the co-ordination of these international studies. In 1955 a base-line as a minimum was agreed upon [12] On the other hand each centre has been free to add further investigations

In January 1955 a *Clinic for the Study of Children s Development and Health* was established at Karolinska Sjukhuset in the Children s Hospital and one more member (I S) joined the team Since the number of tasks increased it was found necessary to include another psychologist in the team

Members of the team from the beginning P Karlberg pediatrician head of the team G Klackenberg child psychiatrist I Klackenberg Larsson psychologist H Lichtenstein pediatrician I Svennberg nurse with special training in well baby clinic work

Members associated later on B Olofgörs psychologist (1/3 1958–28/? 1959) K Widstrom psychologist (1/_ 1959–31/3 1960) J Stenson psychologist (from 1/4 1960)

Scope

The general design of the investigation is as follows (Table 1)

Antenatal interview The psychologist visits the expectant mother in her home 1–2 months before the estimated time of delivery in order to establi h contact and introduce the study A short interview is taken mainly concerned with her attitude towards the delivery what sex she wi hes her child to be and her former experience of children

Investigations at the maternity hospital In a *Lying In interview* the psychologist continues the contact with the mother and goes into her experience in connection with delivery and the child s behaviour during the stay in the maternity hospital

Somatic data The pediatrician commences his field work at the maternity hospital He obtains information on the family history including hereditary diseases the mother s antenatal and obstetric hi tory the course of labour and delivery the child s condition immediately after delivery and during the subsequent time in the maternity hospital

Follow up investigations (the main study) After the maternity hospital period the

child is examined at the clinic at the following ages: 1 month (4 weeks), 3 months (13 weeks), 6 months (*6 weeks), 9 months (39 weeks), 1 months, 18 months, * years and thereafter once a year. In order that the investigations may be considered to represent actual ages the following tolerances a regards time are permitted: for the age of 4 weeks ± * days; for 3–18 months ± 1 week; for –3 years ± * weeks and subsequently – weeks and + 4 weeks.

At each visit the following examinations and observations are made.

Somatic h story is recorded, including a general appraisal of health since the last visit and a *cli ical examination* is performed with a general appraisal of the present condition of health status.

Body measurements are taken for 16 different parts of the body area (Fig. 1) including measurement of the skinf lds at four different places.

Roentgenological examinations of a wrist nkle and knee are carried out in order to estimate the skeletal development judged by the size and shape of the ossification centers. In addition, the calf is also examined to determine the thickness of the soft tissue.

Phot graph of the hild in different positions are taken. From the age of 4 years these re carefully standardized in order t enable assessment of body constitution (Fig. 1).

Psychological nterviews with special reference to the child's functional deve lopment and beha iour. They comprise a set of detailed questions in accordance with standard form and last about one and half hours. They are focused on different habits and trait a well a on the parents method of handling the child.

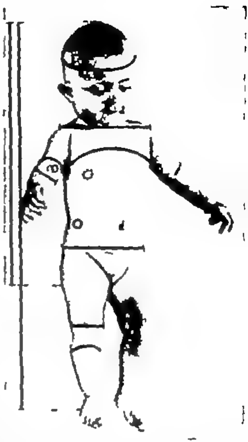

Fig 1. The various body measurements taken.

Up to 3 years these interviews take place only with th mother but when the child is 4 years old the father as well is interviewed (at home). Both parents fill in an attitude scale (bridged Schaefer Bell) [41]. We also ask them about their attitudes to their own upbringing.

Psychological t sting. Starting from the age of 3 months and continuing up to years, a psycho-motoric development test for infants (Brunet Lézine's [4], a modification of the Gesell test) is used. This test is applied also in the majority of the other centres. At the age of 3 years the intelligence level is essed by the Terman Mer

time a random selection of prospective mothers from the clientele of a gynecologist with a private practice in Solna had also been agreed upon. It was found, however, that the 183 children comprising the ANC group taken together with the 29 children of the pilot study afforded a good agreement with the socio-economic class distribution of families in Stockholm (see page 19). A selection from the clientele of a gynecologist would not have been unexceptionable either from a statistical point of view. Therefore the preliminary plan was not carried out.

A contributory factor in stopping of the recruitment at this point was that it continuation would have meant an increase ... which was not considered feasible having regard to the financial ... available at that time.

It was then decided that the material for study should consist of the 183 children from the Solna Antenatal Clinic and the 29 children from the pilot group, making a total of 212 children.

Course of the Study up to the Time when all Children had Reached 3 Years of Age

The recruitment of the 21 children was completed after a period of 3 years; the annual distribution is shown in Fig. ... It also gives the age distribution on 31 March 1961: the oldest children were then 8 years old and the youngest 3.

Losses. On 1 April 1961 there were still 209 children taking part in the investigation. Of 3 children who had so far dropped out, ... had been taken to west Sweden at the age of one year and 1 to the United States at the age of 18 months.

In general the interest shown by the families participating in the investigation has been most satisfactory and in those cases where difficulties have arisen owing to, for instance, the participant's work proving an obstacle or to hesitation in general, the study group has done all in its power to facilitate continued participation. It has been possible for the Clinic to keep in touch also with representatives of more extreme social, economic and

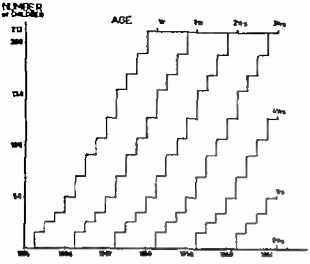

Fig A diagram showing the intensity of recruitment during the time period of 1 April 1955 to 31 March 1958 as well a the age distribution of the material at any quarter of the years up to 31 March 1961 when all children had reached the age of 3 years.

huset is situated in the town of Solna was an advantage of practical significance

Recruitment started in the beginning of 1955 At first a test group of 12 children aged 1–18 months was formed in order to test methods and procedures Of these 7 are still being studied but the data on them will not be included in the analysis of the final material.

Up to December 1955 a pilot group *comprising* 29 *children* was *enrolled* In these cases the first contact was made either antenatally or neonatally They were mainly recruited from the Obstetrical Department of Karolinska Sjukhuset (21 cases) The remainder consisted of expectant mothers with whom contact had been established through the personnel at child welfare centres

From December 1955 subjects were recruited exclusively from the Solna Antenatal Clinic *Every fourth expectant* mother according to her registration number was *asked* whether she was willing to allow her prospective child to participate in the investigation Seventeen of these mothers—in the beginning registered at the Antenatal Clinic—had already moved from Solna before we began to contact mothers the offer was then made to the next 4th expectant mother selected at *random The same procedure* was adopted if mothers were unable to participate for any other reason such as lack of interest on their own part or of their husbands or fiancés (7 persons) In a longitudinal study which on account of the repeated time-consuming and comprehensive investigations may prove burdensome to the family it is inevitable that already at the onset some of the randomly selected participants should withdraw The number of these cases was small however only 3 per cent of all those who were invited to take part in the investigation

Of the 198 mothers who stated that they were willing to participate 0 fell out on account of abortion and 4 on account of the child s death in connection with delivery Furthermore, 5 were excluded because of the premature birth of the child whose weight at birth was under *2000 grams in view of the fact that* such children represent an extreme group with a special course of development [67]

In this way up to April 1958 183 children were recruited from the Solna Antenatal Clinic for the study (= ANC group) A preliminary estimate of the socio-economic *composition of this group showed* a certain shift in the direction of the lower *socio-economic groups as compared* with Stockholm (see discussion on the representativeness *of the material below*) This was expected and as an attempt to counterbalance the selection from an antenatal

chose a random selection of prospective mothers from the clientele of a gynecologist with a private practice in Solna had also been agreed upon. It was found, however that the 183 children comprising the ANC group taken together with the 29 children of the pilot study afforded a good agreement with the socio-economic class distribution of families in Stockholm (see page 19) A selection from the clientele of a gynecologist would not have been unexceptionable either from a statistical point of view Therefore the preliminary plan w[illegible]s not carried out

A contributory factor in stopping of the recruitment [illegible]t this point was that its continuation [illegible]ould have meant an increase in staff [illegible]hich was not considered feasible having regard t[illegible] the financial aid [illegible]vailable at that time

It was then decided that the material for study should consist of the 183 children from the Solna Antenatal Clinic and the 29 children from the pilot group, making a total of [illegible]1[illegible] children.

Course of the Study up to the Time when all Children had Reached 3 Years of Age

The recruitment of the 212 children was completed after a period of 3 years; the annual distribution is shown in Fig 2. It also gives the age distribution on 31 March 1961 the oldest children were then 6 years old and the youngest 3

Losses On 1 April 1961 there were still 209 children taking part in the investigation. Of 3 children who had so far dropped out, 2 had been taken to west Sweden at the age of one year and 1 to the United States at the age of 18 months.

In general the interest shown by the families' participation in the investigation has been most satisfactory and in those cases where difficulties have arisen owing to for instance, the participant's work proving an obstacle or to hesitation in general the study group has done all in its power to facilitate continued participation. It has been possible for the Clinic to keep in touch also with representatives of more extreme social, economic and

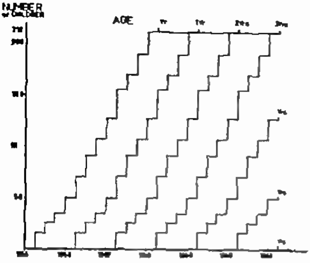

Fig — A diagram showing the intensity of recruitment during the time period of 1 April 1955 to 31 March 1958 as well as the age distribution of the material at any quarter of the years up to 31 March 1961 when all children had reached the age of 3 years.

huset is situated in the town of Solna was an advantage of practical significance

Recruitment started in the beginning of 1955 At first a test group of 12 children aged 1–18 months was formed in order to test methods and procedures Of these 7 are still being studied, but the data on them will not be included in the analysis of the final material

Up to December 1955 a pilot group comprising 29 children was enrolled In these cases the first contact was made either antenatally or neonatally They were mainly recruited from the Obstetrical Department of Karolinska Sjukhuset (21 cases) The remainder consisted of expectant mothers with whom contact had been established through the personnel at child welfare centres

From December 1955 subjects were recruited exclusively from the Solna Antenatal Clinic Every fourth expectant mother according to her registration number was asked whether she was willing to allow her prospective child to participate in the investigation Seventeen of these mothers—in the beginning registered at the Antenatal Clinic—had already moved from Solna before we began to contact mothers the offer was then made to the next 4th expectant mother selected at random The same procedure was adopted if mothers were unable to participate for any other reason such as lack of interest on their own part or of their husbands or fiancés (7 person) In a longitudinal study which on account of the repeated time-consuming and comprehensive investigations may prove burden some to the family it is inevitable that already at the onset some of the randomly selected participants should withdraw The number of these cases was small however only 3 per cent of all those who were invited to take part in the investigation

Of the 198 mothers who stated that they were willing to participate 6 fell out on account of abortion and 4 on account of the child's death in connection with delivery Furthermore 5 were excluded because of the premature birth of the child whose weight at birth was under 2000 grams in view of the fact that such children represent an extreme group with a special course of development (67)

In this way up to April 1958 183 children were recruited from the Solna Antenatal Clinic for the study (= ANC group) A preliminary estimate of the socio-economic composition of this group showed a certain shift in the direction of the lower socio-economic groups a compared with Stockholm (see discussion on the representativeness of the material below) This was expected and as an attempt to counter balance the selection from an antenatal

clinic a random selection of prospective mothers from the clientele of a gynecologist with a private practice in Solna had also been agreed upon. It was found, how ever that the 183 children comprising the ANC group taken together with the 29 children of the pilot study afforded a good agreement with the socio-economic class distribution of families in Stockholm (see page 19) A selection from the lientele of a gynecologist would not have been unexceptionable either from a statistical point of view Therefore the preliminary plan not carried out

A contributory f ctor in stopping of the recruitment t this point was that ts continuation would have meant an increase in staff which wa not considered feasible having regard to th financial id available t that t me

It wa then decided that the material for study should consist of the 183 children from the Solna Antenatal Clinic and the 29 children from the pilot group, making a total of 1 children

Course f the Study up to the Time when all Children had Reached 3 Years of Age

The recruitment of the *L children was completed after a period of 3 years the annual distribution is shown in Fig 2. It also gives the age distribution on 31 March 1961 the oldest hildren were then 6 years old and the youngest 3

Losses On 1 April 1961 there were still 209 children taking part in the investigation. Of 3 children who had so far dropped out had been taken to west Sweden at the age of one year nd 1 to the United States at the age of 18 months.

In general the interest shown by the families participation in the investigation has been most satisfactory and in those cases where difficulties have arisen owing to for instance the participant s work proving an obstacle or to hesitation in general, the study group has done all in its power to facilitate continued participation. It has been possible for the Clinic to keep in touch also with representatives of more extreme social, economic and

huset is situated in the town of Solna was an advantage of practical significance

Recruitment started in the beginning of 1955 At first a test group of 12 children aged 1–18 months was formed in order to test methods and procedures Of these 7 are still being studied but the data on them will not be included in the analysis of the final material.

Up to December 1955 a pilot group comprising 20 children was enrolled In these cases the first contact was made either antenatally or neonatally They were mainly recruited from the Obstetrical Department of Karolinska Sjukhuset (?1 cases) The remainder consisted of expectant mothers with whom contact had been established through the personnel at child welfare centres

From December 1955 subjects were recruited exclusively from the Solna Antenatal Clinic Every fourth expectant mother according to her registration number was asked whether she was willing to allow her prospective child to participate in the investigation Seventeen of these mothers—in the beginning registered at the Antenatal Clinic—had already moved from Solna before we began to contact mothers the offer was then made to the next 4th expectant mother selected at random The same procedure was adopted if mothers were unable to participate for any other reason such as lack of interest on their own part or of their husbands or fiancés (7 person) In a longitudinal study which on account of the repeated time-consuming and comprehensive investigations may prove burdensome to the family it is inevitable that already at the onset some of the randomly selected participants should withdraw The number of these cases was small however only 3 per cent of all those who were invited to take part in the investigation

Of the 198 mothers who stated that they were willing to participate 8 fell out on account of abortion and 4 on account of the child s death in connection with delivery Furthermore 5 were excluded because of the premature birth of the child whose weight at birth was under 2000 grams in view of the fact that such children represent an extreme group with a special course of development [67].

In this way up to April 1958 183 children were recruited from the Solna Antenatal Clinic for the study (ANC group) A preliminary estimate of the socio-economic composition of this group showed a certain shift in the direction of the lower socio-economic groups as compared with Stockholm (see discussion on the representativeness of the material below) This was expected and as an attempt to counterbalance the selection from an antenatal

TABLE 6. *The socio-economic classification of the pilot group the ANC group the total material and families with school-children in Stockholm* (see text)

Social group	Pilot group (= 29) number	%	AKO group (n = 183) number	%	Total sample (= 212) number	%	Stockholm families with schoolchildren (= 238), %
I	(13)	45	(21)	12	(36)	17	16
II	(11)	38	(68)	38	(79)	37	38
III	(5)	16	(93)	51	(98)	46	46

ing distribution was obtained when selecting at random families with boys of school age: Group I 16 %, Group II 38 %, Group III 46 %. When these figures are used for comparison (Table 6) the ANC sample is found to display a slight shift in the direction of a lower social grouping. Such a result could be expected. First, it is probable that expectant mothers who go to antenatal clinics do not entirely represent the society as a whole. Secondly we do *not know exactly* how *similar* the data of social groupings in Stockholm and in Solna are but, as previously shown the differences between the two towns with regard to the distribution of occupations and of votes t the political elections, are inconsiderable (Tables 2 3 and 4) Another possible cause is that the inevitable loss in the line of *every 4th* expectant mother from the Antenatal Clinic may give rise t an undue distribution In order to judge the influence of the last mentioned cause the mothers in question have been *classified* from the socio-economic standpoint A combination of the ANC group and the group *comprising* the loss of cases did not show any significant shift (Group I 10 ., Group II 41 ., and *Group* III 48). Probably the selection from clientele of an antenatal clinic had the greatest influence

The pilot group which represents the minor part (14 %) of the material studied, was recruited mainly from the Obstetrical Department of Karolinska Sjukhuset That these cases were chosen from a hospital population does not in itself imply a selection, since 98.5 per cent of all children in Stockholm, as in other parts of Sweden are born in a hospital [38, 39] On the other hand, the character of the hospital as a university hospital may be of significance This group included also expectant mothers with whom we came into contact through the personnel of child care centres. This probably means a selection of mothers who are *willing* to cooperate. As regards classification into social classes the pilot group showed a *marked shift in the* direction of higher social classes (Table 6)

A combination of the two groups (Table 6) showed very good agreement with the corresponding socio-economic class *distribution* in Stockholm families with boys t school, selected at random [19] Consequently we considered that the two groups together should constitute a material which, from socio-economic point of view should be better representative of *children in Stockholm* and the suburban rea than the ANC group lone

On the basis of the official statistics available in Sweden the representative-

psychological conditions for whom participation might have been expected to be a burden.

Investigations conducted Over 1 800 investigations were carried out Table 5 shows the number of investigations made for the respective ages until the children were 5 years old There were 1,5?0 complete examinations carried out on the correct date The table gives also the number of examinations made on the incorrect date as well as those which were not made at the different ages because of unavoidable circumstances, for example the child s illness or the family being away on holiday

Representativeness of the Material

In a study of growth and development it is essential to know from which population the sample is taken and to what extent it is representative and whether it includes any special features

Selection of material and socio-economic evaluation

The purpose of the study was to investigate children who grow up in a Swedish urban community The town of Solna was chosen as being the most suitable in the region of Stockholm

A perfect random sampling for an investigation of this kind would require among other things a register of all women in Solna who were pregnant during a given time period This was not possible to obtain

A random selection of expectant mothers registered at the only Antenatal Clinic located in Solna was considered the best course within the practical possibilities although this procedure would imply certain limitations. The clientele of a maternity welfare centre cannot be regarded entirely representative of an average population of expectant mothers One can assume even though no direct investigations are available that the most well-to-do and some with a previous bad obstetrical history go to private gynecologists or to an outpatient department of a hospital Moreover other selective factors are conceivable such as the loss of selected expectant mothers who move away before the birth of the child and of mothers who have miscarriages stillbirth or a child who dies neonatally as well as the loss of some women who refuse to take part in the investigations These are all unavoidable circumstances in any investigation of this kind

Consequently the representativeness of the *ABC group* (see page 16) had to be tested In the first place the group was evaluated from a socio-economic point of view A three graded social grouping system widely used in Sweden was employed This pays special attention to paternal occupation (group I represents the highest group [9]) The distribution obtained is shown in Table 6 No comparative classification was available for the town of Solna however and therefore the corresponding figures for Stockholm had to be used

The distribution by social groups in connection with the elections in Stockholm [5? 53] is less suitable for the comparison since it includes all persons eligible to vote young and old married and single There are reasons for assuming that the distribution in such a population is somewhat different from that among families with children More adequate for our evaluation are the findings of Jonsson Kalvesten s investigation of Stockholm boys which they carried out in 19?4–19?8 [10]. The follow

TABLE 6 *The socio-economic classification of the pilot group the ANC group the total material and families with school-children in Stockholm* (see text).

Social group	Pilot group (n = 29) number	%	ANC group (n = 183) number	%	Total sample (n = 212) number	%	Stockholm families with schoolchildren (n = 238), %
I	(13)	45	(21)	12	(35)	17	16
II	(11)	38	(69)	38	(79)	37	38
III	(5)	18	(93)	51	(98)	46	46

ing distribution was obtained when selecting at random families with boys of school age: Group I 16 %, Group II 38 %, Group III 46 %. When these figures are used for comparison (Table 6) the ANC sample is found to display a slight shift in the direction of a lower social grouping. Such a result could be expected. First it is probable that expectant mothers who go to antenatal clinics do not entirely represent the society as a whole. Secondly we do not know exactly how similar the data of social groupings in Stockholm and in Solna are but as previously shown the differences between the two towns with regard to the distribution of occupations, and of votes at the political elections, are inconsiderable (Tables 2, 3 and 4). Another possible cause is that the inevitable loss in the line of every 4th expectant mother from the Antenatal Clinic may give rise to an undue distribution. In order to judge the influence of the last mentioned cause the mothers in question have been classified from the socio-economic standpoint. A combination of the ANC group and the group comprising the loss of cases did not show any significant shift (Group I 10 %, Group II 41 %, and Group III 49 %). Probably the selection from a clientele of an antenatal clinic had the greatest influence.

The pilot group, which represents the minor part (14 %) of the material studied, was recruited mainly from the Obstetrical Department of Karolinska Sjukhuset. That these cases were chosen from a hospital population does not in itself imply a selection, since 98.5 per cent of all children in Stockholm, as in other parts of Sweden are born in a hospital [38, 39]. On the other hand, the character of the hospital as a university hospital may be of significance. This group included also expectant mothers with whom we came into contact through the personnel of child care centres. This probably means a selection of mothers who are willing to cooperate. As regards classification into social classes the pilot group showed a marked shift in the direction of higher social classes (Table 6).

A combination of the two groups (Table 6) showed very good agreement with the corresponding socio-economic class distribution in Stockholm families with boys at school, selected at random [10]. Consequently we considered that the two groups together should constitute a material which from a socio-economic point of view should be better representative of children in Stockholm and the suburban area than the ANC group alone.

On the basis of the official statistics available in Sweden the representative-

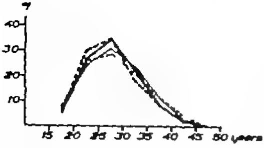

Fig 3

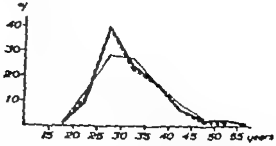

Fig 4

Fig 3 Mothers ages at children s birth —— in ANC group (n = 183) —— in total growth study (n = 12) —— in population of Stockholm 1956–57 —— in population of Sweden 1956–57

Fig 4 Fathers ages at children s birth —— in ANC group (married fathers n = 155) —— in total growth study (married fathers n = 166) —— in population of Sweden (married) 1956–57

ness of the sample can be further evaluated in the first place in respect of parent s age civil status of the mother at birth of the child and order of sequence among the siblings This information is obtained from the investigation of the social and family background (see scope of study) Both the ANC group and the total material have been evaluated in these respects The comparative figures are taken when not stated for the years 1956–1957 during which period most of our children were born

Mother s age (when the child was born)

The mothers age distribution is shown in Fig 3 For purposes of comparison the distributions of mothers in Stockholm [50] and in the whole of Sweden [46] are also given Since the children were recruited irrespective of their order of sequence the diagram represents a mixture of primiparae and multiparae The curves give a cross-section of the mothers ages at child birth There is good agreement especially with the population of Stockholm with a tendency towards younger ages which is less pronounced in the total material than in the ANC group

Father s age (when the child was born)

The fathers age distribution is given in Fig 4 Comparative adequate official data for Solna Stockholm and Swedish urban populations are lacking The comparison that was possible to make covers fathers of children born in wedlock in the whole population of Sweden [20 33] The corresponding ages of the married fathers included in the study are shown in the dashed distribution curve in Fig 4 A tendency towards younger fathers is evident but no difference between the ANC group and the total material

Civil status of the mother (when the child was born)

Out of the 212 children included in the study 89 2 per cent were born in wedlock and consequently 10 8 per cent of the mothers were unmarried. For the ANC group the corresponding figure was 1 [illegible] per cent The number of children born (live births) out of wedlock in Sweden has been rather constant in recent years it is somewhat higher in the town than in the rural districts The percentual mean value for the years 1955–1958 was 10 1 for Sweden as a whole 10 4 for the towns and

0.8 for the rural districts [*8 32 36 37] The corresponding figure for the city of Stockholm is 11.6 [51 54]. Thus the percentage of children who were born out of wedlock corresponds to the mean value for Swedish towns and for Stockholm during the period of recruitment.

It was possible also to estimate the time of delivery in relation to the time when the marriage was contracted. There is good agreement with the official statistics for Stockholm [53] as illustrated in Table 7

Table 7 *Duration of marriage at birth of child*

Duration of marriage at birth of child	ANC group (n = 161) %	Total material (n = 190) %	Stockholm (1956–57) %
< 9 months	26	22	21
9 months–2 years	16	17	16
2 years–5 years	22	24	29
> 5 years	36	37	35

The child's successional number

Table 8 shows the distribution of the children according to their successional numbers at birth. A combination of the ANC group with the pilot group does not appreciably change the figures, nor does a combination of the ANC group with the loss during recruitment To base a comparison on the official Swedish statistics is possible only with regard to children born in wedlock where the marriages were contracted in 1950 or later

Of the Swedish children born in wedlock in 1956 and 1957 2.6 per cent are the issue of marriages contracted in 1950 or later [31 35]. For our corresponding material the figure is 72 per cent (152 children). Conditions in the comparable part of the sample (born in wedlock, marriages contracted in 1950 or later) and the corresponding condition in Solna and other urban population in Sweden are shown in Table 8 Information on the town of Solna is taken from the primary material available at the Central Bureau of Statistics. There is good agreement between our material and comparable figures for the town of Solna

It was possible to judge another aspect of the firstborns who were the issue of marriages contracted in 1950 or later Of these 78 children, 44 per cent were born less than 9 months after the marriage ceremony According to official statistics the corresponding percentage for Swedish firstborns in 1956 and 1957 was 45.5 per cent and 44 per cent respectively [30 34]. Here, the material covered by the study corresponds to conditions which are

ness of the sample can be further evaluated in the first place, in respect of parent s age civil status of the mother at birth of the child and order of sequence among the siblings. This information is obtained from the investigation of the social and family background (see scope of study) Both the ANC group and the total material have been evaluated in these respects. The comparative figures are taken, when not stated for the years 1950–1957 during which period most of our children were born

Mother s age (when the child was born)

The mothers age distribution is shown in Fig 3 For purposes of comparison the distributions of mothers in Stockholm [50] and in the whole of Sweden [46] are also given. Since the children were recruited irrespective of their order of sequence the diagram represents a mixture of primiparae and multiparae The curves give a cross-section of the mothers ages at child birth There is good agreement especially with the population of Stockholm with a tendency towards younger ages which is less pronounced in the total material than in the ANC group.

Father s age (when the child was born)

The fathers age distribution is given in Fig 4 Comparative adequate official data for Solna Stockholm and Swedish urban populations are lacking The comparison that was possible to make covers fathers of children born in wedlock in the whole population of Sweden [20 33] The corresponding ages of the married fathers included in the study are shown in the dashed distribution curve in Fig 4 A tendency towards younger fathers i evident but no difference between the ANC group and the total material

Civil status of the mother (when the child wa born)

Out of the 212 children included in the study 89 . per cent were born in wedlock and consequently 10 8 per cent of the mothers were unmarried For the ANC group the corresponding figure wa 1 0 per cent The number of children born (live birth) out of wedlock in Sweden ha been rather con tant in recent years it is somewhat higher in the town than in the rural di trict The percentual mean value for the years 1955–1958 wa 10 1 for Sweden a a whole 10 4 for the town and

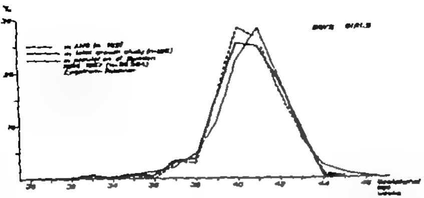

Fig 5. Children's gestational age at birth in the AXO group, in the total material, and in the population of Sweden 1956–57 (Engstrom-Falconer).

are, on the other hand, of greater importance in evaluating the representativeness of the material. The distribution of these parameters is given in Tables 10 and 11. During the period 1 July 1956–30 June 1957 Engström and Falconer made a survey supported by the Government, of weight and length at birth in relation to gestational age for all live-born newborns in Sweden [11]. An analysis of their material was made after the exclusion of twins and triplets, newborns of diabetic or toxaemic mothers, and all children with malformations. After excluding similar

known. The comparison however has a restricted value since as regards first-borns it was not possible to give figures for an urban as opposed to a rural population.

Perinatal factors

Perinatal factors are of importance also for the evaluation of the general properties of the material Table 9 shows the incidence of some significant perinatal factors No higher incidence was found to occur in the pilot group It is hazardous

to draw conclusions concerning the frequencies of factors which occur so seldom in our material. However if an evaluation is made from the annual reports of maternity hospitals in the Stockholm region [69] it would seem that perinatal complications are not overrepresented but possibly slightly underrepresented in our material This may be due to the exclusion of still births and neonatal death and to the small number of prematures. Moreover it is probable that cases with an earlier bad obstetrical history often receive antenatal care at a hospital and not to such a great extent at antenatal clinics The frequency of irreversible damage to children injured by perinatal factors is, however so low that a study designed on the lines of the present investigation can not be expected to afford significant information on these conditions.

Gestational age and weight at birth

TABLE 11 *Distribution of birth weight for boys and girls*

Birth weight in kg	Boys: ANC group (n - 103) n	Boys: Total material (n - 122) n	Girl: ANC group (n - 80) n	Girl: Total material (90) n

are on the other hand, of greater importance in evaluating the representativeness of the material. The distribution of these parameters is given in Tables 10 and 11. During the period 1 July 1956–30 June 1957 Engström and Falconer made a survey supported by the Government of weight and length at birth in relation to gestational age for all live-born newborns in Sweden [11]. An analysis of their material was made after the exclusion of twins and triplets, newborns of diabetic or toxaemic mothers, and all children with malformations. After excluding similar

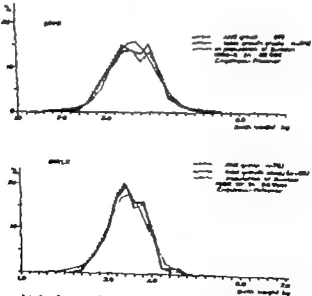

Fig 4. The birthweight for boys and girls in the ANU group, in the total material, and in the population of Sweden 1956–57 (Engström-Falconer).

cases ($n = 13$) the gestational age and weight at birth in the ANC group and in the total material were compared with the results of this survey (Figs 5 and 6). There was good agreement with a slight tendency towards lower values in our material. The evident broader range of birth weight for the boys in relation to the girls in the large Engström–Falconer material is closely followed by our material which supports its representativity.

Sex distribution

Another property of the studied material with importance for its representativity is the sex distribution. The ANC group consists of 56.3 per cent boys and 43.7 per cent girls and the total group of 57.5 per cent boys and 42.5 per cent girls. In the town of Solna 52.1 per cent boys and 47.9 per cent girls were born during the years 1956 and 1957 [43] which means an increased proportion of boys in relation to the whole country (51.6 per cent boys) [47]. The high frequency of boys in our material is nevertheless conspicuous. However a t test does not show any significant percentage difference ($P > 0.05$).

Conclusion

On account of the preliminary socio-economic evaluation recruiting was concluded with the ANC group. The pilot group and the ANC group taken together showed in this respect a better agreement with conditions in Stockholm than the ANC group alone. There are reasons to believe that this holds good for both Solna and Stockholm with its inner suburban area. Further analyses have shown that in other respects such a combination does not seem to affect the representativeness of the material in a negative direction.

The practical difficulties associated with adequate sampling have unfortunately been great. If the children had been selected after birth a sampling technique which was statistically more strict could have been applied. Although the data obtained during the antenatal interview do not form an essential part of the total data collected in our opinion the antenatal contact with each expectant mother and also with many of the fathers was of great value for cooperative participation in the study.

However the group of children obtained by means of the techniques used showed good agreement in most respects when comparisons were possible with conditions known to prevail in the large urban area from which the material originated. Apart from the composition of the social group this applies also to the mothers' age, the percentage of children born out of wedlock, the time when the children were born in relation to the time when marriage was contracted, the children's successional number, the stated period of pregnancy in weeks and the children's weight at birth.

The frequency of boys in relation to that of girls does not differ by more than can be attributed to chance in the differences that exist in statistically unexceptionable samples recruited from the same population group. The difference obtained cannot be due to any special selection because the main group of the sample was chosen before the birth of the children. Nor can this sex distribution give rise to any skewness in the results since in the analyses of the combined data where sex may be regarded as of importance the sampl[illegible]

divided into boys and girls. Only the values obtained for the girls are based on a somewhat smaller number than those for the boys.

A further point to be observed is the composition of the pilot group in which social group I is over represented. On account of the recruiting method applied the pilot group probably contains a higher percentage of mothers who are more willing to cooperate. This should be borne in mind with reference to analyses of data from social group I in the total material.

We have considered it important to carry out these analyses, since the more similarities that can be established, the stronger are the reasons to assume that the study will furnish data that have a wider application than merely to the group investigated. Hence when we subsequently present frequencies and tendencies regarding somatic and psychic data we may do so with a degree of confidence based on the above-mentioned considerations.

Summary

The first Swedish prospective longitudinal investigation into the development of children in a Swedish urban community is presented. Its aims, design and recruiting procedure are described, and the representativeness of the material obtained is discussed. The investigation forms a link in an internationally coordinated study.

cases ($n = 13$) the gestational age and weight at birth in the ANC group and in the total material were compared with the results of this survey (Figs. 5 and 6). There was good agreement with a slight tendency towards lower values in our material. The evident broader range of birth weight for the boys in relation to the girls in the large Engström–Falconer material is closely followed by our material which supports its representativity.

Sex distribution

Another property of the studied material with importance for its representativity is the sex distribution. The ANC group consists of 56.3 per cent boys and 43.7 per cent girls and the total group of 57.5 per cent boys and 42.5 per cent girls. In the town of Solna 52.1 per cent boys and 47.9 per cent girls were born during the years 1956 and 1957 [43], which means an increased proportion of boys in relation to the whole country (51.6 per cent boys) [47]. The high frequency of boys in our material is nevertheless conspicuous. However a t test does not show any significant percentage difference ($P > 0.05$).

Conclusion

On account of the preliminary socio-economic evaluation recruiting was concluded with the ANC group. The pilot group and the ANC group taken together showed in this respect a better agreement with conditions in Stockholm than the ANC group alone. There are reasons to believe that this hold good for both Solna and Stockholm with its inner suburban area. Further analyses have shown that in other respects such a combination does not seem to affect the representativeness of the material in a negative direction.

The practical difficulties associated with adequate sampling have unfortunately been great. If the children had been selected after birth, a sampling technique which was statistically more strict could have been applied. Although the data obtained during the antenatal interview do not form an essential part of the total data collected, in our opinion the antenatal contact with each expectant mother and also with many of the fathers was of great value for cooperative participation in the study.

However, the group of children obtained by means of the techniques used showed good agreement in most respects when comparisons were possible with conditions known to prevail in the large urban area from which the material originated. Apart from the composition of the social group this applies also to the mothers' age, the percentage of children born out of wedlock, the time when the children were born in relation to the time when marriage was contracted, the children's successional number, the stated period of pregnancy in weeks and the children's weight at birth.

The frequency of boys in relation to that of girls does not differ by more than can be attributed to chance in the differences that exist in statistically unexceptionable samples recruited from the same population group. The difference obtained cannot be due to an special selection because the main group of the sample was chosen before the birth of the children. Nor can this sex distribution give rise to any skewness in the result, since in the analyses of the combined data, where sex may be regarded as of importance, the sample i

divided into boys and girls. Only the values obtained for the girls are based on a somewhat smaller number than those for the boys.

A further point to be observed is the composition of the pilot group in which social group I is over represented. On account of the recruiting method applied the pilot group probably contains a higher percentage of mothers who are more willing t cooperate This should be borne in mind with reference to analyses of data from social group I in the total material

We have considered it important to carry out these analyses since the more similarities that can be established, the stronger are the reasons t assume that the study will furnish data that have a wider application than merely to the group investigated. Hence when we subsequently present frequencies and tendencies regarding somatic and psychic data we may do so with a degree of confidence based on the above-mentioned considerations.

Summary

The first Swedish prospectiv longitudinal investigation into the development of children in a Swedish urban community is presented. Its aims, design and recruiting procedure are described, nd the representativeness of th material obtained is discussed. The investigation forms a link in an internationally coordinated study

The Development of Children in a Swedish Urban Community A Prospective Longitudinal Study

II The Social Background and its Changes During the Children's First Three Years of Life

by GUNNAR KLACKENBERG PETTER KARLBERG INGRID KLACKENBERG-LARSSON HENRIK LICHTENSTEIN JAN STENSSON and INGA SVENNBERG

It is a generally accepted fact that a child's growth and development are influenced by the social environment In the present longitudinal study the social data including the family background form an essential part of the investigations (see the scope of the study in Paper I of this series [7])

The detailed analysis of the social environment of the 212 studied children has two main aims 1) evaluation of the representativeness of the studied group of children and 2) evaluation of the relation between the social background with its changes and the child's development The purpose of this report is to provide the base material by describing and defining the social background The representativity of the studied children has been discussed in Paper I [7]

The social data will be divided into the following main groups type of district from which the families were recruited housing condition in respect of occupant density and comfort parents education their occupation source and size of income and composition of the family including age and civil status of the parents Although several of these items will be used separately for later correlative analyses of collected data it is obvious that some kind of condensation of the social data into a social grouping system would be very useful As this Swedish study constitutes a link in internationally coordinated studies (see Paper I [7]) such a system might also form a basis for international comparison At the beginning of these international studies Graffar the leader of the Brussel study group elaborated a social grouping system for this purpose [3] It is based on 5-point scales for five different criteria which include occupation level of education main source of family income quality of dwelling and type of inhabitated district This Graffar system has been applied in the present study and its application will be discussed It will also be compared with the customary Swedish classification into three social groups based mainly on the father's occupation

The picture of the social condition and their changes during the first 3 years of life of the children investigated also have a wider application than to this particular group of children since the sample has been shown to be representative in several respects of children living in Stockholm with its inner suburban area (see Paper I [ ])

Material

The study covers the social background of 212 children with their families. The recruitment took place during the period April 1955–March 1958, and the methods of recruitment have been described in Paper I [7]. The main recruitment area was Solna, town close to Stockholm. Only 3 of the original 212 children participating in the study have been lost sight of during their first three years [7].

Method

The data of social conditions were obtained mainly from interviews with the mothers when the children were 1, 2 and 3 years old. The data recorded are those given in Appendix in Modern Problems in Pediatrics V [4]. Some of these data, for instance the housing conditions, have also reference to the time of the child's birth. Supplementary information has been collected through home visits. In order to ensure a uniform standard of judgement, replies have been scrutinized and discussed within the team.

Owing to the loss of 3 of the 212 children, and since all data were not always obtainable, the calculations of the distribution of different items had to be based on slightly varying numbers. This is indicated, however, in the heading of each table.

The Area in Which the Children Lived

Solna forms a part of the conglomerate of communities which constitute Greater Stockholm. Solna includes within its area a number of newly erected hypermodern blocks alternating with older houses in relatively good repair, and of old residential areas which, without being actually called slums, represent the most unmodern dwellings in the Stockholm of today, without central heating or other amenities. The older houses for one or more families are usually built of wood and have sometimes garden plots. Within the urban district there are also factories, but these do not dominate the scene and consequently the area cannot be characterized as particularly industrial. Though many of the Solna families earn their living in Stockholm, Solna cannot be regarded as the special kind of urban structure known as a "dormitory" (often situated on the periphery of large cities). In Solna there are shops of different sizes, offices, artisans and small-scale factories. The town is in a rapidly progressive phase of its history with the development of new residential areas and modernization of the old ones.

During the children's first 3 years of life, however, a number of their families moved from their original homes. At the age of 3 years the situation of the 209 families remaining in the study was the following:

- 163 families living in Solna.
- 33 families living within the inner suburban area of Stockholm.
- 3 families living within the outer suburban area of Stockholm.
- 10 families living outside Stockholm and suburbs.

Of the ten families who have moved from the Stockholm area, three still live in towns. All ten children have been retained in the study.

In the Graffar system of social grouping one of the five criteria is the type of district in which the families live. This classification is not applicable to Solna, since for the most part there are no distinct demarcations between the different types of district. The Graffar classification is based on areas with bigger differences between districts. Graffar realized [4] that this criteria may be very difficult or even

Acta Pædiatrica Scandinavica Suppl 28–47 1968

The Development of Children in a Swedish Urban Community A Prospective Longitudinal Study

II The Social Background and its Changes During the Children's First Three Years of Life

by GUNNAR KLACKENBERG PETTER KARLBERG INGRID KLACKENBERG LARSSON HENRIK LICHTENSTEIN JAN STENSSON and INGA SVENNBERG

It is a generally accepted fact that a child's growth and development are influenced by the social environment In the present longitudinal study the social data including the family background form an essential part of the investigations (see the scope of the study in Paper I of this series [7])

The detailed analysis of the social environment of the 212 studied children has two main aims, 1) *evaluation of the representativeness* of the studied group of children and 2) *evaluation of the relation* between the social background with its changes and the child's development The purpose of this report is to provide the base material by describing and defining the social background The representativity of the studied children has been discussed in Paper I [7]

The social data will be divided into the following main groups type of district from which the families were recruited housing conditions in respect of occupant density and comfort parents education their occupation source and size of income and composition of the family including age and civil status of the parents Although several of these items will be used separately for later correlative analyses of collected data it is obvious that some kind of condensation of the social data into a social grouping system would be very useful As this Swedish study constitutes a link in internationally coordinated studies (see Paper I [7]) such a system might also form a basis for international comparisons At the beginning of these international studies *Graffar* the leader of the Brussel study group elaborated a *social grouping system for this purpose* [3] It is based on 5-point scales for five *different criteria which include occupation* level of education main source of family income quality of dwelling and type of inhabitated district This Graffar system has been applied in the present study and its application will be discussed It will also be compared with the customary Swedish classification into three social groups based mainly on the father's occupation

The picture of the social conditions and their changes during the first 3 years of life of the children investigated also have a wider application than to this particular group of children since the sample has been shown to be representative in several respects of children living in Stockholm with its inner suburban area (see Paper I [7])

Earth closet outside of the house	24	11	16	8	13	6	13	6

The figures show that dwelling space is very restricted. When the mothers came home from the maternity hospital nearly one third of the families had to live in dwellings with or more persons per room (Table 1).

When the children were 1 year old 22 of the families still lived in these restricted conditions. In these calculations the word room is understood to mean also a kitchen provided it is large enough to sit eat or sleep in. (Practically 100 per cent of the households have their own kitchens: at birth of the children 96 at 1 and 3 years of age 98 %, at 5 years of age 99.5 %.)

The high incidence of restricted dwelling space is not a unique phenomenon for our families. The same is found in Swedish official housing investigation [8]. In a recent socio-psychological study by Jonsson and Kalvesten [6] of a random sample of families with boys of school-age in Stockholm 22 were living in restricted dwelling space. The used as criterion of overcrowding more than persons per room. This is the generally used norm in Sweden [9]. In these calculations however the kitchen is not included as a separate room. If this norm for overcrowding is applied to our study at the birth of the children and on their first and third birthdays then the percentage of overcrowding is more striking: 51, 43 and 28 per cent respectively. When comparing these results it should be borne in mind that Jonsson-Kalvesten's investigations deals with children of school-age and that in our families there is a tendency to less restricted dwelling space with increasing age of the children.

The overcrowding of the families with small children is indeed conspicuous.

Another indication of the living-space standard of family is the extent to which the child has a room of its own or shared with its siblings. The distribution is shown in Table 1. A shift towards better living space with increasing age of the child up to 3 years is again obvious.

Access to modern conveniences

We have taken account of the following conveniences: heating system, water supply, bath and W.C. (Table ?). Fairly modern flat, i.e. with central heating, hot water, bathroom and W.C., are the domi

TABLE 1 *Types of dwelling and dwelling space*

	At birth (– 1)		Age of children 1 year (– 11)		years (– [illegible]01)		3 years (– [illegible]06)

By room is meant also a kitchen provided that it is large enough to sit, eat or sleep in.

impossible to apply in some places and proposed that in such cases only the other four criteria should be used. This is what will be done in the present study.

Housing Conditions

The housing conditions, an important environmental factor for a child's development, comprise several aspects such as type of dwelling, living density and access to modern conveniences. These will first be analysed separately (Table 1 and 2) and then weighted to give a combined housing score.

Type of dwelling

Table 1 shows that more than 90 [illegible] of the families lived in rented flats, which reflects the general trend in Swedish towns [8]. During the children's first 3 years of life there was a small shift toward living in a two-family or one-family house.

Originally some newly established families ($n = [illegible]$) lived in dwellings belonging to near relatives, especially the mother's parents (Table 20). The main cause has probably been the housing shortage in Sweden. Within 3 years all families but one had succeeded in obtaining their own dwellings.

Dwelling space

As regards dwelling space there is a clear tendency to improvement during the children's first 3 years of life. This improvement took place despite the increase in size of the family through the birth of siblings in 40 cases. The improved standard is probably due to the difficulty young families have in getting suitable dwellings in the early years of marriage as well as to the housing policy of the community, which assist families with children.

TABLE 2 *Housing conveniences*

	Age of children							
	At birth (212)		1 year (=211)		2 years (=201)		3 years (204)	
				%	n	%	n	%
Central heating	166	79	165	86	167	83	172	85
Tile stove and/or iron stove (oil coke, electricity)	44	21	43	20	34	17	34	17
Hot water and bathroom	143	67	162	73	154	77	163	79
Hot water no bath	14	7	3	1	5	2	3	1

impossible to apply in some places and proposed that in such cases only the other four criteria should be used. This is what will be done in the present study.

Housing Conditions

The housing conditions, an important environmental factor for a child's development, comprise several aspects, such as type of dwelling, living density and access to modern conveniences. These will first be analysed separately (Table 1 and 2) and then weighted to give a combined housing score.

Type of dwelling

Table 1 shows that more than 90 % of the families lived in rented flats, which reflects the general trend in Swedish towns [8]. During the children's first 3 years of life there was a small shift towards living in a two-family or one-family house.

Originally some newly established families (n = 7) lived in dwellings belonging to near relatives, especially the mother's parents (Table 20). The main cause has probably been the housing shortage in Sweden. Within 3 years all families but one had succeeded in obtaining their own dwellings.

Dwelling space

As regards dwelling space there is a clear tendency to improvement during the children's first 3 years of life. This improvement took place despite the increase in size of the family through the birth of siblings in 49 cases. The improved standard is probably due to the difficulty young families have in getting suitable dwellings in the early years of marriage as well as to the housing policy of the community, which assists families with children.

TABLE Housing conveniences

	Age of children							
	At birth (n = 212)		1 year (n 211)		2 years (= 201)		3 years (= 206)	
		%		%	n	%	n	%
Central heating	168	79	168	80	167	83	172	83
Tile stove and/or iron stove (oil coke, electricity)	44	21	43	20	34	17	34	17

Earth closet outside of the house	24	11	18	9	13	6	13	6

The figures show that dwelling space is very restricted. When the mothers cam home from the maternity hospital nearly one third f the families had to live in d ellings with or more persons per room (Table 1).

When the children were 1 year old, 22 of the families still lived in these restricted conditions. In these calculations the word room is understood to mean also a kitchen provided it is large enough to sit eat or sleep in (Practically 100 per cent of the household have their own kitchens t birth of the children 96 at 1 nd years of ge 98 t 3 years of age 99.5 .)

The high incidence of restricted dwelling space is not a unique phenomenon for our families The same is found in Swedish official housing investigations [8] I a recent socio-psychological study by Jonsson and K lvesten [6] of random sample of f milies with boys of school-age in Stockholm 22 were living n restricted d el l ng pace They used a criterion of over rowding more than persons per room. This is the generally used norm in Sweden [8] I these calculations however the k t hen is not included a a separate room. If this norm for overcrowding is applied to our study at the birth of the children and on their first and third birthdays, then the percentage of overcrowding is more striking 61 43 and 28 per cent respectively When comparing these results it should be borne in mind that Jonsson-Kalvesten investigation deals with children of school-age and that in our families there is a tendency to less restricted dwelling space with increasing age of the children

The overcrowding of the families with small children is indeed conspicuous.

Another indication of the living-space standard of a family is the extent to which the child has a room of it own or shared with it siblings The distribution is shown in T ble 1 A shift towards better living space with increasing age of the child up to 3 years is again obvious

Access to modern conveniences

We have taken account of the following conveniences: heating system water supply bath and W C. (Table) Fairly modern flats, i.e. with central heating hot water bathroom and W.C., are the domi-

nant type. 67 per cent of the flats fulfilled these conditions at the children's birth and 79 per cent of the families had entirely modern flats when the children were 3 years old Improvements in the housing standards can thus be observed not only in the greater living space but also in access to modern conveniences Our figures for housing conveniences especially when the children are 3 years old are in good agreement with the 1960 conditions in Stockholm [8]

The housing conditions for the studied families may be characterized in short by a high incidence of restricted dwelling space but by a high incidence also of access to modern conveniences

An overall evaluation of the housing quality

In a study of this kind it would be convenient to have a grouping system for overall housing quality This is unfortunately not possible by means of a simple formula which moreover should be applicable also for international comparisons To some extent we can express restricted dwelling space in numerical terms, and we can state the extent to which modern conveniences are available but to balance these magnitudes against each other must involve a certain subjective element In an attempt to evaluate the housing quality we have considered that overcrowding should be given great weight On this account we adapted the Graffar 5-point scale to Swedish conditions using the following minimum requirements

Group		
I	Modern	> 1.5 rooms/person
IIa	Modern	1 0 room/person
IIb	Semi modern	> 1 5 rooms/person
IIIa	Modern	> 0 75 room/person
IIIb	Semi modern	> 1 0 room/person
IVa	Modern	> 0.5 room/person
IVb	Semi modern	> 0 75 room/person
IVc	Unmodern	> 1 0 room/person
Va	Modern	< 0.5 room/person
Vb	Semi modern	< 0 75 room/person
Vc	Unmodern	< 1 0 room/person

In a few cases dwellings near the limit values have been moved into the adjacent group on grounds such as the total number and sizes of the rooms or the age composition of the members of the household. This means that if the density figures are the same the restriction of dwelling space is considered to be greater if a household consists more of adults and older children than of younger children

Here are some typical examples of different categories Group II modern dwellings where the family can use at least one room as a sitting room in addition to the bedrooms An example of the usual dwelling in group III is one with 2 rooms and a good kitchen with all modern conveniences for a family with 2 children. A semi modern flat with the same living space and with the same number of occupants is regarded as belonging to group IV and dwellings which are without either central heating or W C are assigned to group V

Table 3 shows the distribution of the different dwelling groups at the various ages of the children The figures indicate an evident improvement during the 3-year period

By the time the children were 3 years old half of the families (52 of 110) who earlier lived in dwellings classified in groups IV and V had moved to bett r

Modern = central heating W C bathroom
Semi modern one or two of these facilities.
Unmodern = none of these facilities

TABLE 3 *Housing quality*

Classification (according to Graffar)	Age of children: At birth (n = 212) n	%	1 year (n = 212) n	%	2 years (n = 209) n	%	3 years (n = 209) n	%
Group I	5	*2*	8	*9*	6	*3*	10	*5*
Group II	19	*9*	30	*14*	38	*18*	49	*23*
Group III	78	*37*	86	*41*	96	*46*	92	*44*
Group IV	72	*34*	64	*30*	47	*22*	41	*20*
Group V	38	*18*	27	*13*	22	*11*	17	*8*

dwellings but at that age 28 per cent of the children still lived in housing conditions that were unsatisfactory

Parents' Education

With regard to education parents have been classified in the following 5 groups (an adaptation of the Graffar classification to the Swedish school system)

Group		Years of education
I	University examination or equivalent education	15–
II	Matriculation examination ("studentexamen") or similar standard, but not university examination	12–13
III	School certificate ("realexamen") or similar standard, but not matriculation	9–10
IV	Legal obligations relating to school attendance fulfilled (elementary school)	6–8
V	Legal obligations relating to school attendance not fulfilled	

The designation "similar" education covers such vocational training as is given in courses or at training institutes which confer qualifications and the right to apply for posts on a level with those afforded by the corresponding school examinations.

Group II for example, includes the following training schools: technical and commercial colleges, schools for registered nurses and special training colleges for teachers. Group III relates to corresponding schools on a lower level

TABLE 4 *Educational grouping*

Educational category	Father 1 year (n = 212) n	%	Mother 1 year (n = 212) n	%	Family, Age of children: 1 year (n = 212) n	%	2 years (n = 209) n	%	3 years (n = 209) n	%
Group I	26	*12*	3	*1*	27	*13*	24	*11*	26	*12*
Group II	22	*10*	23	*11*	31	*15*	32	*16*	31	*15*
Group III	24	*11*	33	*16*	32	*15*	31	*15*	30	*14*
Group IV	133	*63*	147	*69*	122	*57*	122	*58*	122	*58*
Group V		*0*	1	*0.5*	0	*0*	0	*0*	0	*0*
Unknown	7	*3*	0	*0*	0	*0*	0	*0*	0	*0*

nant type. 67 per cent of the flats fulfilled these conditions at the children's birth and 79 per cent of the families had entirely modern flats when the children were 3 years old. Improvements in the housing standards can thus be observed not only in the greater living space but also in access to modern conveniences. Our figures for housing conveniences, especially when the children are 3 years old, are in good agreement with the 1960 conditions in Stockholm [8].

The housing conditions for the studied families may be characterized, in short, by a high incidence of restricted dwelling space but by a high incidence also of access to modern conveniences.

An overall evaluation of the housing quality

In a study of this kind it would be convenient to have a grouping system for overall housing quality. This is unfortunately not possible by means of a simple formula which, moreover, should be applicable also for international comparisons. To some extent we can express restricted dwelling space in numerical terms and we can state the extent to which modern conveniences are available, but to balance these magnitudes against each other must involve a certain subjective element. In an attempt to evaluate the housing quality we have considered that overcrowding should be given great weight. On this account we adapted the Graffar 5-point scale to Swedish conditions using the following minimum requirements:

Group		
I	Modern	> 1 5 rooms/person
II*a*	Modern	> 1 [illegible] room/person
II*b*	Semi modern	> 1 5 rooms/person
III*a*	Modern	> 0 75 room/person
III*b*	Semi modern	> 1 [illegible] room/person
IV*a*	Modern	> 0.5 room/person
IV*b*	Semi modern	> 0.75 room/person
IV*c*	Unmodern	> 1 0 room/person
V*a*	Modern	< 0 [illegible] room/person
V*b*	Semi modern	< 0 75 room/person
V*c*	Unmodern	< 1 0 room/person

Modern – central heating, W C, bathroom.
Semi modern – one or two of these facilities.
Unmodern – none of these facilities.

In a few cases dwellings near the limit values have been moved into the adjacent group on grounds such as the total number and sizes of the rooms or the age composition of the members of the household. This means that if the density figures are the same, the restriction of dwelling space is considered to be greater if a household consists more of adults and older children than of younger children.

Here are some typical examples of different categories. Group II: modern dwellings where the family can use at least one room as a sitting room in addition to the bedrooms. An example of the usual dwelling in group III is one with 2 rooms and a good kitchen with all modern conveniences for a family with 2 children. A semi modern flat with the same living space and with the same number of occupants is regarded as belonging to group IV, and dwellings which are without either central heating or W C are assigned to group V.

Table 8 shows the distribution of the different dwelling groups at the various ages of the children. The figures indicate *an evident improvement during* the 3-year period.

By the time the children were 3 years old, half of the families (of 110) who earlier lived in dwellings classified as groups IV and V had moved to better

TABLE 6. *Permanence of mothers' occupational work*
According to interviews 1, 2 and 3 years after child's birth

	(21?)	% (of 200)
Full time occupation at each investigation	20	10
Either full time or part time at each investigation	9	5
Never any occupational work	117	59
Occupational work on some occasions	54	27
Information lacking for any of the three investigations	12	—

occupational work, for different ages of the child, is distributed between regular and irregular full time and part time employment. Since mother's occupational work is considered a potential factor in the child's development, it is important to point out that none of the mothers had full time occupational work when the child was one month old and 2 months later only 4 per cent of the mothers had started regular occupational work. From 6 months of age up to 3 years there is then a slow gradual increase from 10 to 22 per cent of mothers with regular occupational work.

Mothers who are working "part time irregularly" are those who have casual work, sometimes performed at home at times in the evenings or early mornings. Table 5 shows the occurrence of the mothers' various occupational work at the times when the investigations were carried out, but it does not indicate whether it is the same mothers who are working outside their homes the whole time or not. The permanence of the mothers' occupational work or lack of work is shown in Table 6. During the children's first 3 years of life more than half of the mothers belong to the category of permanent housewives (59 %). Constant full time employment is comparatively rare as long as the children are small (10 %).

Classification of parents' occupations

The Graffar classification system uses five different categories of occupation. It is based on the official British publication, Classification of Occupations (2). The occupations are there grouped as follows:

Group I: professional, etc. occupations
Group II: intermediate occupations
Group III: skilled occupations
Group IV: partly skilled occupations
Group V: unskilled occupations.

This classification has been used for the sake of international comparison [4]. Table 7 gives the distribution of the five categories, for the fathers as well as for the mothers, when the children were 1 year old. When characterizing the occupational category of family the highest of the parents' occupations has been used in accordance with the agreed plan for the international studies. The table also gives the figures for family classification during the first 3 years of life of the children. The real changes, however, are more frequent than this cross-sectional analysis indicates. 16 families went up 1 or 2 categories, 7 families went in the opposite direction. In 9 of the former the change was the result of mothers starting work outside the home; in 4 of the latter group the father had left the family.

During the course of the study, however, it became evident that for several occupa-

TABLE 5 *Mother s occupation*

Table 4 shows the distribution of the fathers mothers and families educational level If the parents educational levels differ the highest has been taken as representative of the family Only one mother has been assigned to group V She went to school only for 2 years due to illness of long duration Only 1/3 of the fathers and about 1/3 of the mothers received education above legal obligations Of the fathers who reached the matriculation examination the majority went on to university or equivalent education but only 3 of the mothers It is difficult to find suitable material for comparison partly because the educational level in Sweden is rapidly changing nowadays with the changing school system

The nearest adequate material for comparison seems to be Härnquist s [5] investigation of the reserves for higher education This material comprises about 10 000 males born between *1928–1936* The fathers in our sample are on average 5 years older but about half of them were born during that period

According to Härnquist 65 of his material (from towns with university) had passed only elementary school Our corresponding figure is 63 Otherwise we cannot compare our figures for the other categories because we have not subdivided them in quite the same way For the higher educational levels comparisons between the two materials will be inadequate also for the reason that the men in Härnquist s material were followed up only until the age of about 20 years.

As expected there have been few changes in the parents education during the children s first 3 years of life

Although this eductional classification seems to be acceptable from a Swedish point of view it cannot be considered to be directly comparable with that of another country due to differences in school system

Parents Occupation

Frequency of maternal occupation

When describing a child s environment in respect of its parents occupation the first aspect we have considered is whether *the mother has occupational work or not* For further elucidation of this question the data given in the social form have been supplemented by information obtained at the psychological interviews when mothers were asked in detail about their work Occupational work is here defined as paid employment usually performed outside the home Table 5 shows how the mother s

TABLE 6. *Permanence of mothers' occupational work*

occupational work for different ages of the child, is distributed between regular and irregular full-time and part-time employment. Since mothers' occupational work is considered as an essential factor in the child's development it is important to point out that none of the mothers had full-time occupational work when the child was one month old, and 2 months later only 4 per cent of the mothers had started regular occupational work. From 6 months of age up to 3 years there is then a slow gradual increase from 10 to 22 per cent of mothers with regular occupational work.

Mothers who are working "part time irregularly" are those who have casual work, sometimes performed at home at times in the evenings or early mornings. Table 5 shows the occurrence of the mothers' various occupational work at the times when the investigations were carried out, but it does not indicate whether it is the same mothers who are working outside their homes the whole time or not. The permanence of the mothers' occupational work or lack of work is shown in Table 6. During the children's first 3 years of life more than half of the mothers belong to the category of permanent housewives (60 %). Constant full time employment is comparatively rare as long as the children are small (10 %).

Classification of parents' occupations

The Graffar classification system uses five different categories of occupation. It is based on the official British publication, Classification of Occupations (2). The occupations are there grouped as follows:

Group I: professional, etc. occupations
Group II: intermediate occupations
Group III: skilled occupations
Group IV: partly skilled occupations
Group V: unskilled occupations.

This classification has been used for the sake of international comparison (4). Table 7 gives the distribution of the five categories, for the fathers as well as for the mothers, when the children were 1 year old. When characterizing the occupational category of family the highest of the parents' occupations has been used in accordance with the agreed plan for the international studies. The table also gives the figures for family classification during the first 3 years of life of the children. The real changes, however, are more frequent than this cross-sectional analysis indicates. 16 families went up 1 or 2 categories, 7 families went in the opposite direction. In 9 of the former the change was the result of mothers starting work outside the home—in 2 of the latter group the father had left the family.

During the course of the study, however, it became evident that for several occupa-

* These figures include some mothers with part time irregular work or work at home.

tions the placing according to the official British list is not in agreement with common social evaluation in Sweden. There are four kinds of occupations among our studied families which seem to us to be placed too low and two kinds of occupations too high. According to the British system an airline pilot and a navigating officer are classified in group III. According to Swedish conditions they should be in groups I and II respectively. Before their appointment to the civil airline the two men had been respectively an officer in the air force and a graduate engineer and would then have been classified under group I in the British system. As civil aviators their social position in the British system would drop to the same level as skilled workers, locomotive, tram and truck drivers (group III).

Under the British system there is no differentiation between different kinds of teachers (group II) such as secondary school and elementary school teachers. In Sweden the former are trained at university and the latter at special training colleges. It is thus reasonable to place the former in the same group (I) as occupations requiring a university education of corresponding duration. For the same reason a veterinary surgeon should be placed in group I instead of group II.

A differentiation between engineers of higher and lower degree seems also to be justified. They generally attain positions of different responsibility correlated to their degree. In the British system, however, they all belong to group I. Engineers who have not studied technology at a university level should be placed in group II. Furthermore, it is strange to us to find drivers of trams, busses, taxi cabs and trucks on the same level as skilled workers who have required a relatively long period of training (group III). We consider the former to belong rather to the group of partly skilled workers (group IV).

If the British classification is modified

TABLE 8. *Parents' occupation (British modified)*

	Age of children					
	1 year (= 212)		2 years (= 209)		3 years (= 209)	
	n	%	n	%		%
Group I	24	11	[illegible]	11	[illegible]	11
Group II	36	17	[illegible]	18	40	19

Group IV	35	17	31	15	33	16
Group V	11	5	[illegible]	6	12	6

in this way the classification changes in 32 cases out of 212 (i.e. 15 %).

Table 8 shows how the families are distributed over the different occupational categories after these modifications

Family Income

Income obviously is an essential factor in family's living arrangements. In planning for the internationally coordinated studies, however, it was considered impossible for some of the participating study groups to obtain information on income. Therefore Graffar introduced as one of his five criteria the more easily ascertained criterion, main source of family revenue. In America Warner (12) has found this criterion closely related to the amount of family revenue. Graffar divides the sources of family revenue into five groups.

Group I: persons whose income is derived from private property

Group II. persons who are self-employed or engaged in independent professions and whose income consists in perquisites, profits or fees

Group III: employees receiving a monthly salary

Group IV: employees or casual labourers receiving wages weekly or daily

Group V: persons who are in receipt of public or private relief of more permanent nature. (This does not include assistance received through sickness or unemployment insurance; in such cases group classification depends upon the manner in which the income is earned under normal conditions.)

On this basis the classification is shown in Table 9

Source or revenue has turned out to be a less suitable variable for Swedish conditions. First, we do not find the close relation between source of revenue and amount of family income (Table 1*) as reported by Warner [1*]. On the contrary the correlation between the two variables is only .19 which is much lower than any other correlation between the social grouping variables (see also page 40 where the interrelation between several variables is discussed). Secondly the material is distributed mainly among the three middle categories.

We have considered the taxable income to be a better measure of financial status.

It has been possible to obtain this information in 98 % of the families, and we shall thus use it as an alternative to source of income.

We have set the limits for the income groups at 5000, 10,000, 18 000 and 30,000 Swedish crowns. On account of changes in monetary value during the years of

In this way the classification changes in 32 cases out of 212 (i.e. 15 %).

Table 8 shows how the families are distributed over the different occupational categories after these modifications.

Family Income

Income, obviously is an essential factor in a family's living arrangements. In planning for the internationally coordinated studies, however, it was considered impossible for some of the participating study groups to obtain information on income. Therefore Graffar introduced as one of his five criteria the more easily ascertained criterion, main source of family revenue. In America Warner (12) has found this criterion closely related to the amount of family revenue. Graffar divides the sources of family revenue into five groups:

Group I persons whose income is derived from privat property

Group II persons who are self-employed or engaged in independent professions and whose income consists in perquisites, profits or fees

Group III employees receiving monthly salary

Group IV employees or casual labourers receiving wages weekly or daily

Group V persons who are in receipt of public or private relief of a more permanent nature (This does not include assistance received through sickness or unemployment insurance in such cases group classification depends upon the manner in which the income is earned under normal conditions.)

On this basis the classification is shown in Table 9.

Source or revenue has turned out to be a less suitable variable for Swedish conditions. First we do not find the close relation between source of revenue and amount of family income (Table 12) as reported by Warner (12). On the contrary the correlation between the two variables is only 19 which is much lower than any other correlation between the social grouping variables (see also page 40 where the interrelation between several variables is discussed). Secondly the material is distributed mainly among the three middle categories.

We have considered the taxable income to be a better measure of financial status.

It has been possible to obtain this information in 98 % of the families, and we shall thus use it as an alternative to source of income.

We have set the limits for the income groups at 5000 10 000 15,000 and 30 000 Swedish crowns. On account of changes in monetary value during the years of

study the nominal values have been adjusted to the level of the year 1955 according to the consumer price index issued by the Swedish Social Welfare Board. The distribution of family incomes during the children s first three years of life are shown in Table 10

As expected this variable has a better distribution over the whole range of the income scale

Social Grouping

In the preceding pages we have presented several variables each of which describes one aspect of the social situation of a family In many instances it is more convenient and practical to have if possible some kind of measure which sums up the total social situation even if this method has some disadvantages [1]

In Sweden the most commonly used social grouping is a division into three categories (Table 11) This is mainly based on a grouping of occupations It crudely differentiates between upper middle and working classes

For the international investigation of which this study is a part Graffar [3] has developed a socio-economic classification including the following variables

1) dwelling 2) occupation, 3) education 4) source of revenue 5) type of district inhabitated The fifth variable has been impossible for us to use, so we have excluded it (in accordance with Graffar s instructions) By adding the figures of the different variables for each family one obtains the total figure indicating the socio-economic level of the family As the range in each variable is 1 5 the variability of the total score is from 4 to 20 (when the fifth variable is excluded) This scale will be referred to as Graffar total score Graffar has also combined the 16 degrees of the scale into 5 social classes in the following way·

Total score 4–7 = social class I
Total score 8–10 = social class II
Total score 11–13 = social class III
Total score 14–16 = social class IV
Total score 17–20 = social class V

In the previous pages we have discussed some inadequacies when adapting this system to Swedish conditions This holds mainly for the two variables "grouping of occupations and „source of revenue By introducing the earlier mentioned modifications in the grouping of occupations and by replacing source of revenue by amount of income and by excluding district in

Modified occupation	16	7
Education	4	1
Source of revenue	0	15
Income grouping	58	16
Dwelling	57	14
Social class (according to Graffar)	36	10
Social class ("modified")	48	6
Social group (Swedish system)	10	5

parently because both differentiat labourers from other employees.

The correlation coefficients are higher for the modified occupation scale than for the original one.

Generally it may be said that none of the correlations are so high as to justify exclusion of any one of the variables. Each of them seems to contribute a rather large portion of specific variance so that a combined scale might give a rather good overall measure of the social status of a family.

Changes in Social Conditions During the First Three Years

When describing the different social variables, we have pointed out the changes that have occurred during the period. In Table 13 the data are summed up to give an overall view of the changes up to three years. There is a distinct trend towards improvement of the social conditions during the period. This is evident particularly as regards income and dwelling, whereas educational standard usually does not change. The improvement of the social conditions is recognized also in a shift towards higher social class in many families. In the modified social class scoring, 48 families moved to a higher group and only 6 families to a lower one. Only in 65 families were no changes whatsoever registered during the period.

These changes probably reflect a development towards the stabilization of the social status of the youngest families as well as the general increase of social standard in Sweden during these years.

Family Data

The family situation of the children will be described by the following family data: age of parents, completeness of family

TABLE 14. *Parents' age at children's birth*

years	16–19 n	%	20–24 n	%	25–29 n	%	30–34 n	%	35–39 n	%	40–44 n	%	45–49 n	%	50– n	%

Graffar social class							87

habited we have obtained a modified total score and modified social class

We shall use the original Graffar system mainly for international comparisons. Table 11 shows the distribution of our families in the different social grouping systems.

The different variables of Graffar's original and our modified social grouping system are all with the exception of educational level approximately normally distributed during the years under consideration The modified scales seem to be somewhat better than the original ones also in this respect

Concerning the two versions of total score a tendency towards bimodal distribution can be observed in the present material (Figs 1 and 2) In the original Graffar scale the bimodality is present already when the children are 1 year old, while in the modified scale it seems to be a gradually developing process in this direction The division line is at circa 10 points at 3 years which separates out the *roughly* 25 % having the best social conditions.

Intercorrelations Between Different Social Variables

It is neither meaningful nor possible to give a complete report of all the different relations between the social variables here but we may consider a few important intercorrelations.

Table 12 shows the intercorrelations between the variables belonging to the original and the modified Graffar socio-*economic scales*[1]

Note the extremely low correlation between the two variables which are supposed to measure the family's economic standard. It is only 19 and thus a good deal lower than any other correlation in the matrix On the whole moreover the two measures of income show a rather low correlation to the other variables *Source of revenue* however correlates rather well with occupation (48 with the original and .51 with the modified) ap-

[1] The original Graffar scale consist of British Occupation Education, Source of Revenue Dwelling Our modified scal consist of Modified Occupation, Education Income and Dwelling

TABLE 13 *Changes in social group variables from 1–3 years*

civil status of the mother number and order of siblings and other members of the family

Parents age at birth of the child

The age distribution (grouped in 5-year intervals) for the mothers and fathers is given in Table 14 Compared with available figures for the population of Stockholm and Sweden respectively there is good agreement though with a slight tendency towards younger ages in our families

The father is some years older than the mother which shows the same trend as in the Swedish population as a whole The mean age of the mothers was at the children s birth 27 4 years and the range 15–42 years. Corresponding figures for the fathers were 30 1 years and 19–54 years

As evident from Table 15 there are significant differences in mean age both for fathers and mothers between the lowest social group (Swedish group III) on the one hand and the higher groups (Swedish I + II) on the other In the two latter groups the parents are about 2 3 years older

Completeness of the families

89 % (n = 189) of the children in the sample were born in wedlock (of these, 24 % during the first 8 months of the marriage) The remaining 11 % were born out of wedlock.

When evaluating the family situation it is important to recognize that some of the unmarried mothers were living with the child s father under conditions resembling marriage From the child s point of view such family like conditions may be considered similar to those of a child whose parents are formally married This is especially true when the parents get married later as happened in 9 out of the 16 incidences within 3 years after the child s birth. Four couples continued to live together without being married For the remaining 3 children the parents separated

TABLE 16 *Birth in relation to time of wedlock in different social groupings and variables*

during the first 3 years, which may be considered as comparable with the situation when a marriage is dissolved.

Even so, we have made a comparison of the social status between the following three groups (Tables 16 and 17):

A. The child born out of wedlock
B. The child born within 8 months of marriage
C. The child born more than 8 months after marriage

Table 16 shows that children born out of wedlock belong to greater extent to lower social groupings, 3/4 of them to Swedish social group III. The differences between the groups A and C are statistical significant ($P < .01$)

In group A (born out of wedlock) the parents ages at the children's birth are low and differ significantly from those in group C. The mean ages in group A are 23.7 years for mothers and [illegible] years for

TABLE 17 *Proportion of children born to unmarried, 8 months and more than 8 months married parents in different social groups*

Swedish social group	A – out of wedlock		B – within 8 months of marriage		C – after 8 months of marriage		Total
	n	%	n	%	n	%	n
I	0	*0*	4	*11*	31	*89*	35
II	6	*8*	14	*19*	58	*73*	79
III	17	*17*	26	*27*	55	*56*	98

fathers Corresponding figures for group C (conceived in wedlock) are 29 for mothers and 31 9 years for fathers (Table 18)

It is evident that from a social point of view the children born out of wedlock are an unfavoured group a fact to bear in mind in comparisons This holds true also in comparison with group II where the parents ages do not differ significantly from those in group A The ages of parents, then do not seem to be a decisive factor in the differences

The home situation of the 200 children can be summarized as follows.

For 101 children the family was *complete*

181 couples married during the 3-year period
7 couples living together and later married
3 couples living together unmarried

For 13 children the family was *broken up*

6 couples married at birth of child, later divorced
6 couples living together unmarried, later separated (one temporarily married)
1 couple father in inebriates home child in foster home

For 5 children the family was *never complete*

the mother being unmarried and never living with the father of the child. However this very seldom means that the children lived without any other grown ups than theirmother (only 2 children)

For 18 children whose families were *broken up or* had *never* been *complete* the family situation when the children were 3 years old was as follows

4 children in foster homes
3 children in children s home
11 children lived with their mothers, of them ha ing a stepfather

Tables 19 and 20 show the cross-sectional changes of the parents civil status and the children s home situation

Number of children and order of sequence

The average number of children per family is 1 9 at the children s birth.

Table 21 shows the inconsiderable per centual differences in the distribution of children of different birthorder in the various social classes.

49 children got a younger sibling during their first 3 years of life, none more than one 29 of these were firstborns. Table 22 shows the order of birth of the children in relation to number of older as well as *younger siblings*

Total number of members in the household

Table 23 shows the distribution of the sizes of households when the children are 1 2 and 3 years of age At all ages the majority of households consist of 4 persons The natural development towards larger households is reflected in the figures but some of the largest households (6 or more persons) decreased owing to the parents moving away from their relatives when they obtained their own dwelling

Summary

The social conditions of the 212 families participating in the longitudinal study during the children s first three years of life are described with reference to 23 tables and 2 figures in respect of housing standard education occupation and income The material is classified under each of these *variables on a 5-grade scale* in accordance with an international social grouping system (Graffar) The aggregate values of the different variables are considered to reflect the socio-economic level of the family

A modification of the international system has been applied that is better adapted to Swedish conditions.

Calculations of the correlations between the different variables and between them and the total social score show no such high coefficients as would justify the exclusion of any variable on that account

A third social classification that has been used is the 3-grade scale based on occupation ı commonly employed in Sweden.

Family data are reported, comprising the age of the mother and father composition of family mother s civil status and time of conception in relation to date of marriage. The incidence of children born out of wedlock was 11 %. Their unfavourable social conditions are demonstrated.

The social status of the entire sample underwent a manifest improvement during the children s first three years of life The main improvement was in the housing standard. An improvement of real income was also noticeable While 5.. per cent of the children lived in unsatisfactory housing condition at birth, the figure was 28 per cent at 3 years of age As regards mother occupation only 15 per cent had half-time or full time employment from one to three years after the child s birth.

In so far as comparisons could be made with adequate official statistics and published studies of social conditions and family data the agreement has been good.

The Development of Children in a Swedish Urban Community. A Prospective Longitudinal Study

III. Physical Growth during the First Three Years of Life

by PETTER KARLBERG, INGA ENGSTRÖM, HENRIK LICHTENSTEIN and INGA SVENNBERG

A child's physical development is a complex phenomenon which can be fairly well described by means of several body measurements. The more numerous the measurements, the more differentiated will be the picture obtained, even though height and weight alone can often give valuable information.

Knowledge of physical development and its normal variations is a necessary tool in assessing a child's state of health, as the course of an illness and the influence of treatment, among other factors, often affect growth and are reflected by it.

In assessing a single measurement of a child, data from cross-sectional studies of healthy children can be used for comparison. For the purpose of assessing the rate of growth of children by repeated measurements, standards based on cross-sectional data are inadequate. They give only mean values with standard deviations at each age. The means are often connected to form a line which simulates an average individual's development. But this method provides no answer to the question: What are the normal limits of the deviation from the slope of the constructed curve? Such information can be obtained only by longitudinal studies, where repeated measurements of each child are made at regular intervals over a period of time. The longitudinal method yields not only data on distance, that is, the child's size attained at each age, but also on the difference in attained distance between the ages, which is best described as an increment and thus represents the rate of growth.

This paper presents longitudinal data relating to the physical development during the first three years of life of Swedish children in an urban community.

Recruitment took place over the years 1955–1958 and data used in the present study were collected between 1955 and 1960.

For the planning of the study and other details, see Paper I in the series [8].

Material and Methods

The study comprised originally 212 children, 122 boys and 90 girls. By the time the children had reached the age of 3 years, 3 had dropped out because the families had moved abroad. Length, weight and

head circumference were measured at birth. Thereafter the children were examined on eight occasions until the age of 3 years, namely at 1 month (4 weeks), 3 months (13 weeks), 6 months (26 weeks), 9 months (39 weeks), 12 months (52 weeks), and at 18 months, 2 years, and 3 years. Each examination was made on an exact date with a variation of ± 1 day at 1 month, ± 1 week from 3 months to 18 months and $\pm$ weeks from 2 to 3 years.

As from the age of 1 month the examinations included body measurements according to a carefully standardized programme which listed the following 16 measurements:

Weight—nude weighing, up to 15 kg with an accuracy of 0.01 kg and thereafter with an accuracy of 0.1 kg.

Length as *recumbent length* and *crown-rump length*, measured with the child lying supine on a special table fitted with a measuring tape and sliding footboard; the measurements were made with an accuracy of 0.1 cm.

Femur bicondylar and *humerus bicondylar widths* measured with the knee and the elbow respectively flexed at 90°; *biacromial* and *pelvic widths* measured between the most lateral points of the acromion and the iliac crest respectively; special metal calipers graded in mm were used.

Head circumference and *chest circumference*, the latter measured at the level of the mamilla at mid-respiration; *upper-arm* and *calf circumferences* recorded as maximum circumferences at passive flexion of the elbow and the knee respectively; a metal tape graded in mm was used.

Subcutaneous tissue measured at four sites, over the *biceps* and *triceps* and *subscapularly* and *subiliacally*. A skinfold was lifted

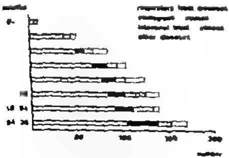

Fig. 1. Number of children with various illness experiences (including only the most important ones) during the intervals between examinations.

and its thickness measured with the Harpenden Skinfold Calipers [3] graded in 0.2 mm. The mean of three measurements was used

Anterior fontanel measured as the shortest distance between parallel bone edges with a metal tape graded in mm

For further details see Falkner F., Mod. probl. in ped V 1960 Chapter VI page 70 [4]

At the measuring sessions the children were examined clinically and any illnesses they might have had since the previous visit were recorded From these data the child's present health as well as its health retrospectively between the visits could be assessed With very few exceptions, all the measurements and assessments were made by the same paediatrician (H. L.) throughout.

State of Health of the Sample

In order to use the obtained measurements for analyses of the normal growth pattern it is necessary to assess the state of health of the children in the group

Table 1 shows the examiner's assessment of the present health of the children, that is, at the time of the examination, in relation to health since the last visit It will be seen that the great majority of the children were considered to be in good health at the time of the examination and that about half of them had had some illness during the interval between the visits. Contagious diseases without complications, banal respiratory tract infection occasional diarrhoea minor operations, and accidents were regarded as conditions of probably no significance in the development of the child Diseases, judged as having either a questionable or a significant influence on the child's development occurred relatively sparsely Only 6 children were considered to have been severely ill during the period of investigation.[1]

In Fig 1 is a graphic representation of the diseases judged to have been the most important during the intervals between examinations

Respiratory tract infection was clearly the most common illness and increasingly so as the children grew older

Children who had had no disease throughout the whole period of investigation (the first 3 years of life) must be regarded as extremes. As our material is representative in so many respects (Paper I) it may be assumed that the state of health and the illness experiences found in the group are characteristic of a normal child population. Therefore no child was excluded from the group for reasons of health.

Longitudinality of the Sample

A pure longitudinal sample with each child attending every measuring session would of course be ideal in a longitudinal study But with such strict criteria it would be almost impossible to obtain a non-selected group since such a pure longitudinal sample can be assumed to consist of the very healthy children and/or the most conscientious mothers.

longitudinal sample	110	70	180	85
rest sample	12	20	32	15
Total sample	122	90	212	100

Table 2 shows the grouping of the material by attendance frequency. The pure longitudinal sample, that is, children who attended all the eight examinations, comprises 52 %, and the group attending all but one examination 32 % of the material. For augmentation of the longitudinal group

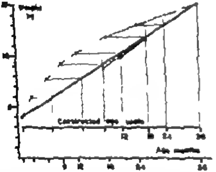

Fig. 2. Graphic interpolation of missing body measurements for given ages taking into consideration the curvilinear relationship to age. The figure shows the procedure used for weight. The curvilinear relationship described by the line connecting the found mean values for each studied age (— —), has been transformed into a rectilinear line by construction of a new age-scale (along the abscissa) in the following way: The plots for the mean weight at 1 and 36 months are connected by a straight line. The obtained mean values of weight for the ages 3, 6, 9, 12, 18 and 24 months are moved horizontally to that line. By vertical lines from these points a new age-scale is constructed. An example is given of interpolation of a missed 12 month value (x—) using the constructed age-scale. Note the graph can only be applied to ages used for its construction.

we considered interpolation of length, weight, and head circumference justifiable in those cases where the children missed one measuring session, excluding those 7 children who failed to attend at 1 month and at 3 years, respectively. Interpolation was made by a graphic method (Fig. 2) on the basis of the mean values derived from the pure longitudinal group.

In 15 % of the sample the children missed two or more examinations, the figures for non-attendance being evenly distributed over the period of examination. This group is referred to as the rest sample. It also includes the 6 ill children. The rest sample was tested against the longitudinal sample: no significant difference was obtained. (Out of 256 analyses only 3 showed significant differences at the 5 % level, which is within the range of variability of the statistical methods.) The two groups were therefore brought together into total sample, which was used for the analyses.

Results

The total sample was used for calculations of means and percentiles. As regards increments, the material is slightly smaller owing to some missed values.

Mean values with S.D. both for distance and for increments were calculated for each body measurement and each age (= exami-

and its thickness measured with the Harpenden Skinfold Calipers [3] graded in 0.2 mm. The mean of three measurements was used

Anterior fontanel measured as the shortest distance between parallel bone edges with a metal tape graded in mm.

The percentiles were also calculated (10th, 25th, 50th, 75th and 90th percentiles) both for distance and for increments. These values are set out in Appendix 3 and 4.

The mean values at the different ages for lengths, widths, circumferences, and weight are shown graphically for distance in Fig 3 and for increments in Fig. 4. As regards increments, the values are in the figures not recorded as the difference between the values obtained on the particular occasions, as these represent the changes within a varying period of time, 2, 3, 6 or 12 months, depending upon the fixed intervals between the examinations. For the sake of uniformity and comparison, increments were therefore converted into values representing a 3-month period. T illustrate the relative growth and the relative change in growth velocity the means for distance and increments respectively at the various ages were plotted on a semilogarithmic scale and connected by lines.

Skinfolds as representative of the subcutaneous tissue do not always increase with increasing age, which means that increments can be negative. Therefore, these

values cannot be rendered logarithmically So for the sake of uniformity both distance and increments for skinfolds are shown on a metric scale in Figs 5 and 6 For comparison, the weight is also shown

A numerical sex difference with preponderance for boys is noted in all the measurements, excluding those of skinfolds, where there is a preponderance for the girls. The found sex differences are significant in most of the cases (Table 3)

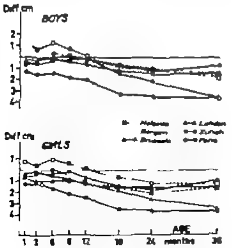

Fig 7 Deviation from present study in mean length at the various ages in studies from London [13], Paris [9], Brussels [5], Zürich [6], Helsinki [1] and Bergen [10].

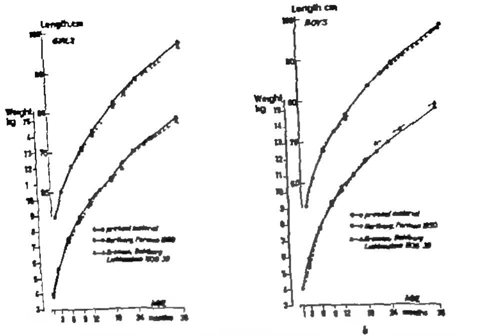
Discussion

It is evident that growth, in general, for all the variables, particularly in the first half year of life occurs at a high but gradually decreasing rate The relative growth in length and in widths is on the whole similar The growth in total length is more rapid, however than the crown-rump growth which illustrates the well known fact that the legs grow quicker than the trunk.

Head circumference and chest circumference are evidently similar for each age during the whole period. But a tendency to more rapid growth in chest circumference during the second year of life is noted.

The relative gain occurs faster in weight than in length widths, and circumferences, in accordance with the fact that weight is three-dimensional whereas the others are one-dimensional.



Figs. 8a and 8b Graphical comparison of mean length obtained in present and previous Swedish studies [2, 7].

The difference in length between boys and girls seems to be due mainly to greater total length and less to greater crown-rump length in boys. As femur and humerus bicondylar widths are also significantly greater in boys than in girls, it seems that particularly the extremities are bigger in the boys. Another striking observation is that the head is constantly bigger in boys than in girls throughout the series.

As regards weight, the values are also higher for boys than for girls, but the difference is not so highly significant as for the bony width measurements. The only body measurement that shows a numerical difference in favour of the girls is that of skinfolds, indicating a greater amount of subcutaneous fat in girls. This difference, however is significant only at the age of 3 years. The poor significance may imply that the random error of the method is greater because of the difficulties in standardizing the technique of measuring.

The fact that the girls have more subcutaneous fat than the boys may account for the small difference in weight between the sexes, in spite of greater length and bony widths in the boys. The small differences in arm, calf, and chest circumferences as well as in pelvic and biacromial widths between the sexes could also be explained by the greater amount of subcutaneous fat in the girls included in these measurements.

The basic difference between boys and girls up to age 3 thus seems to be a predominance of skeletal tissue in boys and of subcutaneous tissue in girls.

A comparison between our values for length and the values obtained in the coordinated longitudinal studies from London [13] Paris [9], Brussels [5], and Zürich [6]

(Fig 7) shows that the Swedish children agree best with the Zürich children and least with the Paris children. The latter are in general 1–4 cm shorter than the Swedish children

In the graphs are also plotted the difference between the Swedish values and the ones obtained in cross-sectional studies from Bergen [10] and Helsinki [1]. The Helsinki children are taller than the Swedish children during the first year of life but tend to be somewhat shorter later on. The Bergen children are from one year of life 1–2 cm shorter than the Swedish children. It must be taken into consideration however that at age 3 the Bergen children were measured in the standing position, which gives lower figures than do measurements in the recumbent position [12]

The means for length and weight are graphically compared (Figs. 8*a* and *b*) with earlier Swedish values [7 2] The values in the present study are in close agreement with those obtained by Karlberg & Perman [7] in the years 1950–52, which form the standards used in Sweden for children up to 1½ years. These values, in turn are very close to those found in a previous Swedish study of weight during the first 12 months of life in children with a birth weight of 3 0–3.5 kg [11] Earlier Swedish investigations of length in this age group are not available for comparison. Swedish standards for the ages above 1½ years are based upon the study published by Broman Dahlberg & Lichtenstein in 194? [2] sampled in 1938–39 These values are thus 20 years older than those obtained in this study In this period of time it would be reasonable to expect a secular trend The slight difference between the children in the present and in the earlier study however is difficult to evaluate as the older values are based upon only a few measurements in each group (around 35) with a wide age range (6 months)

Summary

The physical growth was followed longitudinally from birth to 3 years of age in a group of 212 randomly sampled children from the Stockholm urban area 122 boys and 90 girls. The children were measured on eight occasions at fixed intervals.

Recumbent length crown–rump length weight femur bicondylar and humerus bicondylar width biacromial and pelvic width, circumference of head and chest, subcutaneous tissue at four different sites and the anterior fontanel were measured.

The mean values for these measurements with S.D as well as the percentiles are given The increments were calculated and are also given as means with S.D and percentiles.

The pattern of growth is discussed. Differences between boys and girls were found, particularly with respect to the skeletal and the subcutaneous tissue the former being more developed in boys and the latter in girls.

Acta Paediatrica Scandinavica Suppl. 187 67-93 1968

The Development of Children in a Swedish Urban Community A Prospective Longitudinal Study

II Data on the Mental Development During the first Five Years

(as measured by Brunet Lézine Psychomotor Development Test and Terman-Merrill Intelligence Test)

by INGRID KLACKENBERG-LARSSON and JAN STENSSON

This paper presents some data concerning the mental development of children from 3 months to 5 years of age obtained in a longitudinal study on the development of Swedish children in an urban district.

The sample is composed of 212 children (122 boys and 90 girls) from Solna a town near Stockholm for which area it is found t have good representativeness. (For information regarding the general outline of the longitudinal study and the representativity and social composition of the sample see Papers I and II of our series [10 11])

Thi Swedish study forms a link in a group of international studies, coordinated by International Children s Centre in Paris.

Test Methods and Procedures

In accordance w th the established base line for these coordinated growth studies, the ch ldren were tested on ight occasions t the ages of 3 6, 9 1., 18 and 4 months by Brunet Lézine s psychomotor dev lopment test [4 5], a French adaptation of Gesell' development schedule and at 3 and 5 years with the Terman Merrill intelligence test (1937 revised edition Form L) [13]

The Brunet-Lézine test consists of 10 items at each age Four of them consist of questions to the mother about the child s bilities.

A total development quotient is computed as well as quotients for four subscales. a) Motor development b) Coordination development, c) Language development and d) Social Personal development.

Language items in Terman-Merrill have been analysed separately Further the language development up to 5 years has been studied by means of ratings (see Appendix 1)

In tests on children up to 2 years of age the mother or substitute (in a few cases) was always present. At 3 years the child was tested at one end of the room, while its mother was interviewed by another psychologist at the other end, because of the difficulties of separating a child from its mother at this early age

At 5 years mother and child were separated, generally without any difficulty

DQs and IQs

Results

In the strictly longitudinal and the total sample the means and standard deviations for the raw quotients were calculated and the results are given in Table 2. As will be seen the means are almost identical.

Table shows that only at 24 months the mean quotient is about 100 and thus on the level with the norms of Brunet-Lézine and that at all other ages the obtained means are abo e these norms most markedly at 3 and 6 months (DQ = 114) and at 5 years of age (IQ = 111) (Terman-Merrill).

The standard deviations also vary at different ages. At 3 months nd 3 years the deviation is about 17 and varies from 9.5 to 1 between 6 months and years. The total quotients have therefore been scaled so that the means are 100 and the standard deviations 16 at all ages in order to facilitate comparisons over ages.

Because of the different loss in different social classes and sexes in the strictly longitudinal sample the total sample will form the main basis for the further analysis in this report.

Subscales Table a shows the raw mean quotients for 1) motor 2) coordination, 3) language and 4) personal-social development from 3 months to 4 months of age in th Brunet Lézine test A striking feature is the high level at 3 and 6 months of age within the motor and social spheres. The coordination scale is that in which the mean quotients are most uniform between the ages.

Frequencies of solution of the items in the Brunet Lé ine test The frequencies of sol tion of the items are on the whole very high. The median value in our sample is 78% compared with Brunet-Lézine's 68%. Several items seem to be placed at too high an age level for our children, e.g. "turning from supine to stomach" is placed at 8 months but 74% of our children can do this already at 6 months (26 weeks) by Gesell it is placed at 24 weeks. Such items as "to eat with spoon" and "to drink from cup" our children also perform at an earlier age than the French norms assume.

On the other hand, such an item as "to ask for the pot" has specially low frequency of solution. At 18 months of age it is solved only by 15% of our children. The items which seem to be most adequately placed for our children at all ages are the coordination items.

Discussion

When the Swedish study was planned, no infants scale was standardized for Swedish children and we therefore had to choose among tests from other countries. In the parallel European C.I.E. studies Brunet-Lézine [4] and Griffiths [1] tests were used.

The Griffiths scale, used in the parallel London study is a fairly recent standar dization for British children. We felt most inclined to use this test, as being more suitable for us. The Brunet-Lézine test however was recommended in the baseline for the coordinated studies and used in most of the parallel international studies (in Brussels, Paris and Zürich).

There are some features in the Brunet Lézine test which may need some comments.

The number of items in the different subscales varies from age to age. The reason for this is that development is ir regular the development in one ability

The Accomplishment of Planned Study

It is unavoidable in a study like the present one which covers an age period of [illegible] years that some children will leave the study and some will for various reasons be unable to come at all set ages for examination Consequently there have been some missed examinations among the different ages, as can be seen from Table 1 A strictly longitudinal group i.e a sample in which each child has been examined at each age from 3 months to 5 years, will thus be restricted to 85 boys and 55 girls, altogether 140 children (= 66 % of 212 children)

The loss in the strictly longitudinal sample is unevenly distributed over the social classes and differs between boys and girls as will be seen below

	Swedish social class (at one year)					
	Class I		Class II		Class III	
	n	%	n	%	n	
Boys	8	40	14	*8	15	*7
Girls	12	80	1	41	11	4
	*0	57	6	33	*6	*7

Calculations were therefore also made on a cross-sectional sample including all children tested at a certain age (in somewhat varying numbers n = 193–206) and here called the total sample

Five children in both samples in whom DQ and IQ were not obtained were excluded Four children in the strictly longitudinal sample who were tested beyond the internationally established time limits were also excluded These time limits are at 3 6 9 12 months ± 2 weeks, at 18 months 2 3 and 5 years ± 4 weeks

DQs and IQs

Results

In the strictly longitudinal and the total sample the means and standard deviations for the raw quotients were calculated and the results are given in Table 2a. As will be seen, the means are almost identical.

Table 2 shows that only at 24 months the mean quotient is about 100 and thus on the level with the norms of Brunet-Lézine and that at all other ages the obtained means are above these norms most markedly at 3 and 6 months (DQ = 114) and at 5 years of age (IQ = 111) (Terman-Merrill).

The standard deviations also vary at different ages. At 3 months and 3 years the deviation is about 17 and varies from 9.5 to 12 between 6 months and 2 years. The total quotients have therefore been scaled so that the means are 100 and the standard deviations 16 at all ages in order to facilitate comparisons over ages.

Because of the different loss in different social classes and sexes in the strictly longitudinal sample, the total sample will form the main basis for the further analysis in this report.

Subscales. Table 3 shows the raw mean quotients for 1) motor, 2) coordination, 3) language and 4) personal-social development from 3 months to 24 months of age in the Brunet-Lézine test. A striking feature is the high level at 3 and 6 months of age within the motor and social spheres. The coordination scale is that in which the mean quotients are most uniform between the ages.

Frequencies of solution of the items in the Brunet-Lézine test. The frequencies of solution of the items are on the whole very high. The median value in our sample is 78 %, compared with Brunet-Lézine's 68 %. Several items seem to be placed at too high an age level for our children, e.g. "turning from supine to stomach" is placed at 8 months but 74 % of our children can do this already at 6 months (26 weeks); by Gesell it is placed at 24 weeks. Such items as "to eat with spoon" and "to drink from cup" our children also perform at an earlier age than the French norms assume.

On the other hand, such an item as "to ask for the pot" has specially low frequency of solution. At 18 months of age it is solved only by 15 % of our children. The items which seem to be most adequately placed for our children at all ages are the coordination items.

being more pronounced at one age than at another But from other points of view this uneven distribution of items between the different categories at different ages has some disadvantages. The correlations e.g between ages may be lowered by changes in the factor structure of the test

It seems that the personal-social subscale is heterogeneous According to the authors it includes consciousness of oneself relations to other persons, adaptation to social situations and the games played by the child Our children can for instance be very forward in one aspect of the personal social area and at the same time very backward in another For instance, 84 % of our 18-month-old children solve the item to imitate simple actions of an adult placed at 21 months while they show a low ability (16 %) to solve the 18-months item to ask for the pot (The toilet training in Sweden seems now-a days to start comparatively late probably because of the common use of paper diapers which facilitates the mothers work)

With regard to our high quotients at 3 and 6 months, it should be mentioned that Brunet and Lézine do not recommend the calculations of DQs before the age of 4 months They point out that the DQs will be too high owing to the fact that an addition of a 3-day credit for an item at an early age is proportionally greater than at a later age [4] The same tendency can be seen in the results from coordinated studies using Brunet Lézine test [8 27]

In conformity to Griffiths [12] we find high standard deviations at the earliest age. She considers this to be attributable partly to a purely statistical floor effect She therefore corrects her figures by adding eight weeks both to *the mental and the chronological* age during the first eight months.

The fact that DQs are lower at 2 years may partly be due to ceiling effects. The more advanced 18-month-old children have more and better chances of showing their ability than have the advanced 2 year olds. The clever 18-month-old baby may try items from 21 –4 and 30 months level. For the clever 2 year-old infant however

there are no test items for 27 months; the next step is from now on 6 months instead of 3. Further, if a 2-year-old happens to solve an item on the 3-year level, this is not counted in the subscales, which finish at 2½ years.

Regarding individual items, it cannot be expected that all will be given an optimal suitability in character and age level, especially when the test is worked out for another country. For clinical use in Swe-

being more pronounced at one age than at another. But from other points of view this uneven distribution of items between the different categories at different ages has some disadvantages. The correlations e.g. between ages, may be lowered by changes in the factor structure of the test.

It seems that the personal-social subscale is heterogeneous. According to the authors it includes consciousness of oneself, relations to other persons, adaptation to social situations and the games played by the child. Our children can for instance be very forward in one aspect of the personal-social area and at the same time very backward in another. For instance 84 % of our 18-month-old children solve the item "to imitate simple actions of an adult" placed at 21 months while they show a low ability (15 %) to solve the 18-months item "to ask for the pot". (The toilet training in Sweden seems now-a-days to start comparatively late, probably because of the common use of paper diapers which facilitates the mothers' work.)

With regard to our high quotients at 3 and 6 months it should be mentioned that Brunet and Lézine do not recommend the calculations of DQs before the age of 4 months. They point out that the DQs will be too high owing to the fact that an addition of a 3-day credit for an item at an early age is proportionally greater than at a later age [4]. The same tendency can be seen in the results from coordinated studies using Brunet-Lézine test [8, 27].

In conformity to Griffiths [12] we find high standard deviations at the earliest age. She considers this to be attributable partly to a purely statistical floor effect. She therefore corrects her figures by adding eight weeks both to the mental and the chronological age during the first eight months.

The fact that DQs are lower at 2 years may partly be due to ceiling effects. The more advanced 18-month-old children have more and better chances of showing their ability than have the advanced 2 year olds. The clever 18-month-old baby may try items from 21, 24 and 30 months level. For the clever 2 year-old infant, however

den the Brunet-Lézine test would gain by revision in some respects to make it more adapted to Swedish children.

The Terman-Merrill test has been adapted to Swedish children of preschool ages 1942 by Hellström [13] and by D Katz 1950 [20]. Hellström has translated the whole scale. Her adaptation is the one most commonly used in Sweden and has also been used by us. Her sample was almost exclusively recruited from day nurseries and nursery schools in Stockholm She has not aimed at a representative sampling She has only about 30 children at e.g 3 and 5 years. Katz also found it difficult to obtain a sample representative of the whole country He reports mainly values from a Stockholm sample, which is of greatest interest as a comparison with our results. He has 81 and 89 children at 3 and 5 years of age.

Our mean quotients at 3 and 5 years are higher than the 97 and 100 reported by Hellström.

The corresponding values of Katz are 102 and 108 and thus more similar to ours (104 and 111)

Hellström gives no S.D.s for separate ages. Our S.D.s at 3 and 5 years (17.0 and 13.7) are in good agreement with those of Katz (3 years 16.6 and 5 years 12.2).

Our results, which are based on a sample which is considerably bigger than Hellström's and which appears to have good representativeness for Stockholm, make it probable that her values are too low for contemporary Stockholm children of preschool age.

Correlation Between Different Ages

Results

In order to analyse how constant a child's quotient is from one age to another Pearson correlation coefficients were calculated for boys and girls in both the total sample and the strictly longitudinal sample. The obtained results are shown in Table 3

The differences between the samples are small, with a slight tendency towards somewhat higher values in the total sample The correlations for the girls are often lower than for the boys, especially in the strictly longitudinal sample, where the boys correlations are significantly more often higher than are those of the girls according to the sign test (at the 0.05 level) In this sample the correlations of the girls are especially low between * × 3 years and 2 × 5 years.

Discussion

Our correlations are similar to those found by most other investigators. Table 4 summarizes the correlations between different ages reported by some other investigators (without considering whether the samples are comparable from all points of view) Most authors agree that infant tests are of very little long-term predictive value The correlations between the closest age groups are generally substantial but decrease rapidly with increasing age intervals. As the children grow older the correlation coefficients between test values are higher

Like most others, we can thus state that as regards *normal* children we cannot predict from the 3-12 month values anything about 3-year or 5-year values. Bayley [2], when discussing the low predictive value

TABLE 3 *Correlation of DQs and IQs between different ages Total sample (T) and strictly longitudinal sample (L)*

The number f children in the different correlations varies between 1[illegible] and 180 in the total sample In the strict longitudinal sample the num ber is 140 85 boys, 55 girls.
Parentheses signify correlations which not differ significantly from 0

den the Brunet Lézine test would gain by revision in some respects to make it more adapted to Swedish children.

The Terman-Merrill test has been adapted to Swedish children of preschool ages 194[illegible] by Hellström [13] and by [illegible] Katz 1950 [20]. Hellström has translated the whole scale. Her adaptation is the one most commonly used in Sweden and has also been used by us. Her sample was almost exclusively recruited from day nurseries and nursery schools in Stockholm. She has not aimed at a representative sampling. She has only about 30 children at e.g., 3 and [illegible] years. Katz also found it difficult to obtain a sample representative of the whole country. He reports mainly values from Stockholm sample, which [illegible] of greatest interest as a comparison with our results. He has 61 and 89 children at 3 [a]nd 5 years of age.

Our mean quotients at 3 and 5 years are higher than the 97 and 100 reported by Hellström.

The corresponding values of Katz are 102 and 108 and thus more similar to ours (104 and 111).

Hellström gives no S.D. for separate ages. Our S.D.s at 3 and 5 years (1[illegible] [illegible] and 13.7) are in good agreement with those of Katz (3 years 16.[illegible] and 5 years 13.3).

Our results, which are based on a sample [w]hich is considerably bigger than Hellström['s] and which appears to have a good representativeness for Stockholm, make it probable that her values are too low for contemporary Stockholm children of preschool age.

Correlation Between Different Ages

Results

In order to analyse how constant a child's quotient is from one age [illegible] Pearson correlation coefficients were calculated for boys and girls in [illegible] the [illegible] sample and the strictly longitudinal [illegible]. The obtained results are shown in [illegible]

The differences between the samples are small, with a slight tendency towards somewhat higher values in the [illegible]. The correlations for the girls are [illegible] lower than for the boys [illegible] in the strictly longitudinal [illegible] [illegible] the boys correlations are [illegible] often higher than [illegible] according to the [illegible] level). In the [illegible] girls are especially [illegible] and [illegible] years.

Discussion

Our correlations are [illegible] found by [illegible] [illegible]

Like [illegible]

Sand and Emery Hauzeu [25]: Brunet-Lézine

Sontag et al. [26]: Binet.

of infant tests, summarizes the explanations for this by saying that "scores could be altered by emotional climate, cultural milieu and environmental deprivation on the one hand and by developmental changes in the nature and composition of the behaviours tested on the other"

Developmental Level in Relation to Gestational Age, Sex, Socio-Economic and Family Factors

The developmental level of the children at different ages has been related to the following factors. the gestational age at birth, sex, total social groupings as well as special socio-economic factors and family data such as mother's age, her gainful employment, child's birth order and the time for conception of the child.

Group differences have been compared and tested by χ^2 and t-test.

Relation to Gestational Age at Birth

In tested developmental level during the period close to the birth the gestational age may play a role, greater the closer the test is to the birth.

We have therefore related the length of pregnancy to the DQ values at 3 6 9 and 12 months.

The following four groups were compared by χ^2 analysis:

Gestational age at birth 41 weeks, DQ above the mean	Gestational age at birth 41 weeks, DQ above the mean
Gestational age at birth > 41 weeks, DQ below the mean	Gestational age at birth 41 weeks, DQ below the mean

Result

	χ^2	P
at 3 months	11 13	.001
6	5.51	.02
9	6 44	.01
12	0 72	–

The marked relation between long period of pregnancy and high DQ at 3 month decreases at 6 and 9 months and disappears fully at one year

Discussion

Our results point in the same direction as Cavanaugh's *et al.* although the groups are not divided in quite the same way [6] Comparing IQs of premature mature and postmature infants at 6 12 18 and 36 months, they found at 6 months the means for the postmature group significantly higher than for the mature (0 05 level) At 12 months of age the means for the two groups were identical and thereafter there were no significant differences.

The children may obviously differ greatly in development at an early age, owing to the differences in length of pregnancies. This may contribute to the high standard deviation at 3 months.

Relation to Sex

Results

As will be seen from Table 2a significant differences between the sexes in favour of the girls exist at 18 months 2 years and 3 years with significances at the 0.01 0 001 and 0 05 level respectively (scaled quotients) The difference is greatest at 2 years with an average difference of 8½ points.

We have investigated whether during the years when they are found, the sex differences are evident in all social classes. As seen in Table b this is not so In Graffar intermediate social class (*III*) there are no significant sex differences from 18 months to 3 years, while they are most pronounced in Graffar lowest social class (IV + V) (0 05 level at 18 months and 0 001 at

• years of age) In the highest social class (I+II) there is a tendency in the same direction at the same ages (0 10 level)

The differences between the sexes are especially apparent in the *language* and *personal-social* scales, as will be seen in Table 6 As regards language ability significant differences exist at all ages except 6 months. The girls lead is most marked from 12 4 months of age Since some uncertainty attaches to the 3-month language item and the language items t proximate age levels (.. and 4 months) show no significant difference between the sexes, we do not attach importance to the significant sex difference at 3 months of age.

As regards the personal-social sphere it should be pointed out that, during the period when the girls lead is most marked, this is in the dressing and toilet-training items. The item in which girls are definitely most dvanced is putting on shoes

Another "social" item with highly significant sex difference is asking for the pot

Table 6 shows the differences between the sexes for all items in the Brunet-Lézine test that are significant at least on the 0 01 le el.

As is known, the Terman-Merrill test, which was used for measuring the development t 3 and 5 years of age is not divided into subscales. But we can elucidate some spects of the subsequent language development t 3 and 5 years through two sources 1) language items in the Terman-Merrill test and) ratings of language development by the psychologist

A regards the *Terman Merrill language items* we chose for *3-yea -old* the picture vocabulary item as it is most closely equivalent to one of the language items at 2 years.

We divided the children into two groups: 1) those who could name at least 14 pictures, and 2) those who could name at most 13 pictures According to a χ^2 test there was no significant difference between the sexes (see Table 6)

For the *5-year-old* we chose the Terman-Merrill vocabulary test" as a measure of language development. The children were divided into two groups: 1) those who could define" at least 5 words and 2) those who could define at most 4 words.

Nor did the χ^2 test show any significant difference between the sexes at 5 years of age (see Table 6)

Five-point scales were used for the *psychological rating* of the children s speech development, 1 denoting lowest and 5 highest degree The language aspects assessed at 3 and 5 years of age were: 1) enunciation, 2) maturity of language use (length and complexity of sentence formation and vocabulary in use) and 3) comprehension of language. (For detailed definition of the 5 points of the scales see appendix 1)

At 3 years of age but not at 5 the χ^2 test shows significant differences in favour of girls in all three areas, at the 0 01 level for enunciation and comprehension of language; at the 0 05 level for maturity of language use (see Table 6)

Discussion

Some authors have found significant sex differences during the preschool years, others have not.

From the parallel studies significant sex differences have been reported by H Fischer [8] In the Zürich study most

marked at 18 and 24 months in favour of girls. From the Brussels study [27] however E. A. Sand and C. Emery Hauzeur report no difference although they used the same test (Brunet-Lézine)

In the London study where the Griffiths test was used, a slight, though not significant, tendency to higher mean scores was found for girls at 18 months [14] (at 3 years of age the London children were not tested by Griffiths test)

In the second sample of the Fels study [28] the same tendency was noticeable as in our study the sex difference being greater at and 3 years of age than at 5 years.

N Bayley found no differences in her Berkeley study

These diverging results may be due to differences between countries but are more probably associated with other factors

A factor which may be of significance is the composition of the various samples In our study the sex differences do not appear to be evenly distributed over the social classes but occur mainly within the lowest class. If this applies also to other studies, it may explain that sample where the lowest social class is not represented in due proportion does not show any sex difference

Another factor may be the use of different test items, some of which are more sex-differentiating than others

Many of the items in Bayley s mental scale for example most closely resemble those in Brunet Lézine s coordination scale where in our material no significant sex differences are found either Bayley s scale on the other hand, does not comprise the most sex-differentiating items used by us, e.g those concerning dressing and toilet training Nor does it include our most sex-differentiating language items: to name oneself by Christian name.

The girls lead in language development t an early stage has been confirmed by many authors. McCarthy reports fourteen major studies of the average length of sentences at ages of the 18 months to 9½ years. Of the 64 comparisons between boys and girls, 43 are in the girls favour and only 18 is in the favour of th boys.

If one considers the seven studies reported by McCarthy from 18 months to 3 years of age, one finds that, of the 23 comparisons made, almost all, 21 are in the girls' favour and only one is in the favour of the boys. According to McCarthy sampling errors were involved here in that the girls of that age group came in undue proportion from the lower socio-economic levels [22] In McCarthy s study of the language development of the preschool child (ages 18–54 months) she reports the greatest sex differences as percentage comprehensible responses at the ages 18 and 24 months. The girls gave 38 % and 78 % comprehensible answers at 18 and 24 months respectively and the boys 14 % and 49 % [23] Young [31] found language differences between the sexes to be more pronounced in children of lower socio-economic status. This points in the same direction as our finding of developmental level as a whole.

As regards dressing behaviour Gesell [10] reports a marked sex difference

Summarizing the results as regards sex differences up to 5 years, no significant differences are generally found during early infancy During the next 2 years there is evidence of a more rapid develop-

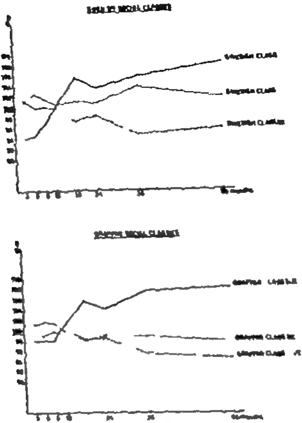

Fig. 1 Mental development in relation to social class.

ment rate for the girls, especially in the language and personal-social spheres. This tendency seems to be most pronounced in the lowest socio-economic class. Later there is a period of less pronounced differences indicating catch-up of the boys.

Relation to Socio-Economic Factors

The socio-economic background of each child was evaluated by means of two different systems: one Swedish, 3-grouped scale and one 5-point scale according to Graffar. The latter is based on five different partial factors (for further details see paper II of our series).

The overall social groupings (Graffar and Swedish social classes) as well as the special factors of housing standard, assessed income, occupation and mother's educational level were related to the scaled total quotients from 3 months to 5 years and to subscale quotients of the Brunet Lézine from 3–4 months.

The differences in mean quotients were tested by the *t*-test.

Results

Developmental level and overall social groupings. Table 7 and Fig. 1 show the *total scaled quotients* for children classified

according to both Graffar scale and Swedish scale. Since there were few children referable to Graffar extreme classes classes I+II are combined to one as well as IV+V According to Swedish grouping, the children of the highest class have significantly lower DQs than the other two classes at 3 and 6 months. The same tendency although never significant can be seen in Graffar social classes. As from 18 months of age, on the other hand, the children in the highest class re significantly more developed

These class differences from 18 months are not found in all *subscale quotients* of the Brunet-Lézine test but only in the coordination scale (Table 7)

The further relation of language development (at 3 and 5 years) to social grouping were studied by Terman Merrill items and ratings (cf page 011) As seen from Table 6 significant differences were found between social classes both in Terman-Merrill items and in ratings. The children in the highest class are throughout most and the lowest class least developed.

Development level and special socio-economic grouping When studying the relation of the level of mental development to housing standard, income occupation of the family and level of education of the mother we divided the children into a high and a low group for each of these factors. The results are shown in Table 8 It is only the parents income that at 3 and 6 months, is significantly related to the total *DQs* parents with the highest income having the least developed children. A relation in the opposite direction is earliest manifested in respect of mother s educational level and the family s occupational status (from 18 months) At 3 and 5 years, however the children with better conditions in all four socio-economic scales have significantly higher IQs.

The relation of the special socio-economic factors to subquotients from 3 months to years is shown in Table 8. The main results are: At an early age parents in the *low income* group have children with higher *DQs* in the motor (3 months) coordination (3 and 6 months) and personal-social (3 months) spheres.

Significant differences in the opposite

according to both Graffar scale and Swedish scale. Since there were few children referable to Graffar extreme classes, classes I+II are combined to one, as well as IV+V. According to Swedish grouping the children of the highest class have significantly lower DQs than the other two classes at 3 and 6 months. The same tendency, although never significant, can be seen in Graffar social classes. As from 18 months of age, on the other hand, the children in the highest class are significantly more developed.

These class differences from 18 months are not found in all *subscale quotients* of the Brunet-Lézine test but only in the coordination scale (Table 7).

The further relation of language development (at 3 and 5 years) to social grouping were studied by Terman-Merrill items and ratings (cf. page 011). As seen from Table 6 significant differences were found between social classes both in Terman-Merrill items and in ratings. The children in the highest class are throughout most and the lowest class least developed.

Developmental level and special socio-economic grouping. When studying the relation of the level of mental development to housing standard, income, occupation of the family and level of education of the mother, we divided the children into a high and a low group for each of these factors. The results are shown in Table 8. It is only the parents' income that, at 3 and 6 months, is significantly related to the total *DQs*, parents with the highest income having the least developed children. A relation in the opposite direction is earliest manifested in respect of mother's educational level and the family's occupational status (from 18 months). At 3 and 5 years, however, the children with better conditions in all four socio-economic scales have significantly higher IQs.

The relation of the special socio-economic factors to *subquotients* from 3 months to 5 years is shown in Table 8. The main results are: At an early age parents in the low income group have children with higher DQs in the motor (3 months), coordination (3 and 6 months) and personal-social (3 months) spheres.

Significant differences in the opposite

low socio-economic grouping are more developed at 3 and 6 months of age. It is, however only in one of the partial factors the income, that this difference is significant. Possibly this could depend upon the fact that the high income group (1+2) is the altogether smallest group It amounts only to 13 % of the entire sample (at 1 year) as against, for instance 28 % for the high occupational group. But even if we cut off a similar small percentage of occupational and educational scales, we still do not get significant differences at 3 and 6 months in these two partial scales.

Relation to the Gainful Employment of the Mother

The mother's being at home or not is supposed to be of great significance in the development of the child. We have compared the developmental level of children of gainfully employed mothers and others The first group consisted of mothers employed part time or full-time, when the children were 1 [illegible] and 3 years of age Group 2 consisted of children whose mothers were at home at the same ages. The number of mothers who had continuous employment during the first 5 years of life of their children was too small to constitute a separate group (n=9). At 5 years, therefore, we compared the children of mothers employed and not employed only at this age

Results

As will be seen from Table 9 there is no significant difference in development level between the two groups at any age

Relation to Mother's Age

The maternal age in our sample varies between 15 and 42 years at the birth of the child The situation of the young mother may differ from that of older mothers in many respects. Young mothers have e.g the less satisfactory financial and housing conditions

We divided the children into three groups according to maternal age 1) children of young mothers (<25 years) 2) children of medium-aged mothers (25–32 years), and 3) children of older mothers (>32 years)

Results

Table 10 shows the scaled mean quotients within these groups from 3 months to 5 years of age

As will be seen, there is no significant difference between the groups before the age of 2.

direction are found between the high and the low groups of occupation and mother's educational level. The high group children are more developed in coordination at 18 and 24 months.

Mother's educational level is the only factor related to the language DQ and this already from 12 months ($t = 1.96$ almost 0.05 level). The significance level rises successively to 0.02 at 18 months and 0.01 at 2 years. Also at 3 and 5 years there are significant differences in language development between children of mothers with high and low educational level, most pronounced at 5 years (see Table 6) again in favour of the more educated goup.

Discussion

An increasing relation between development level and socio-economic status during the preschool years has been reported by several workers (e.g. Bayley [2] Hindley [15] Honzik [17] Sand Hauzeur [27]. Some find significant differences as early as 18 months and 2 years of age (Bayley, Sand Hauzeur) others not until 3 years (Hindley, Honzik). Our observations point in the same direction.

The course of this differentiation process is however far from clear.

"Social class" and "total development quotient" are collective terms for different not always closely related factors. By examining the relations between socio-economic special factors and quotients for the subscales in the test one gets a clearer idea of the role and development of different factors, and relations which are otherwise concealed may come to light. The positive relation between social class and developmental level is found as early as 18 months in our material and this depends mainly upon the significantly differentiating partial factors of family occupation and mother's educational level.

A correlation between the parents' level of education and the mental development of children has been reported by several authors.

Van Alstyne [30] in her study from 1929 of 75 children aged 3 years in New York City reports a correlation of 0.60 between the children's intelligence (measured by Kuhlman-Binet's test) and the mother's education, and of 0.51 with father's education.

Nancy Bayley [1] in her study from California found a negative correlation between the parents' educational level and infant development but after 1 year the correlation became positive and between 1 and 2 years increased sharply, the better educated parents having children with higher mental development. In a recent report [3] from a study of American children from 1–15 months, she finds no difference in developmental level on the basis of educational level of either father or mother.

We found no significant difference in language development during the first two years, using social class classification while as early as 1 year there are almost significant differences in language development between children of mothers with different educational level. This relation becomes gradually stronger at 18 months and 2 years. Mother's educational level seems thus to be the most important factor and the children's language the sphere where one can trace this influence earliest. Using only overall social class this early association would have been overlooked. The children from

Results

The mean quotients of the three groups are shown in Table 11 First-born compared with second children seem to be more advanced during the first 2 years; at 6 and 9 months and years the difference is significant in relation to second born.

W have also compared the mean quotients for the subscales in Brunet Lézine for the first born and second-born at the ages when there are significant differences in the total quotients.

At 6 months it is particularly in the motor and social spheres that the mean differences in favour of the first-born are greatest, although significant in all spheres. At 9 and 24 months the first-born are still superior in motor development, although less markedly so

In coordination there is a significant difference only at 6 months, while there are significant differences in language development between first- and second born at 6 9 and 4 months. The level of significance decreases in all spheres except in language, where it becomes higher with increasing age

At 2 years the means for the children of old mothers are unusually low (93.8); the *difference from that of the children of young mothers is significant.*

At 3 and 5 years there is a significant difference between the children of medium aged and young mothers and likewise between the children of medium-aged and older mothers. In all cases the children of medium-aged mothers have the highest quotients.

The various age groups were also compared with regard to the subquotients from 3 months to 2 years. The results are presented in Table 10.

The children of young compared with medium-aged mothers have a tendency to better motor development, especially at 3 and 6 months when the differences are significant.

As regards language development the children of older mothers are on a very low level at 2 years of age (92.3) when they *differ significantly* from the children both of young and of medium-aged mothers.

Relation to Order of Birth

The order of birth of a child in the family is often considered to be of significance in its development. Is any difference in mental development level noticeable between children with different successional number in the family? What is the effect, for example, of the greater attention and the *perhaps often rather anxious care* devoted to the first-born child?

Our material was divided into three groups—two of roughly equal size, first-born ($n = 84$) and second born ($n = 90$) while third and *subsequent children* ($n = 38$) constitute the third group.

TABLE 11 *Means of scaled total quotients from 3 months to 5 years by children's birth order of illegitimate and legitimate children, of children conceived before and after marriage as well as mean quotients for subscales of first-born and second-born children from 3 to 24 months*

Results

The mean quotients of the three groups are shown in Table 11. First-born compared with second children seem to be more advanced during the first – years; at 6 and 9 months and years the difference is significant in relation to second born.

We have also compared the mean quotients for the subscales in Brunet Lézine for the first-born and second-born t the ages when there are significant differences in the total quotients.

At 6 months it is particularly in the motor and social spheres that the mean differences in favour of the first-born are greatest, lthough significant in all spheres. At 9 and 24 months the first-born are still superior in motor development al though less markedly so.

In coordination there is a significant difference only at 6 months, while there are significant differences in language development between first- and second born at 6 9 and 24 months. The level of signif icance decreases in all spheres except in language, where it becomes higher with increasing age.

In ratings of language development at 3 and 5 years the only significant difference between first-born and others is in enunciation (0 05 level) at 3 years (see Table 6)

Ratings were also made of the children's vocal communicativeness from 1 to 5 years of age on a 5-point scale 1 representing the lowest and 5 the highest degree of communicativeness. First born and others were compared by χ^2 testing with respect to rated communicativeness. At 2 and 3 years there is a significant difference between first-born and others (0 005 and 0 02 respectively $\chi^2 = 12\ 66$ and $8\ 788$ $df = 2$) Also at 18 months there is a tendency in the same direction (0 10 $\chi^2 = 4.718$ $df = 2$) At these ages the first born are throughout the most communicative At one and five years the differences are not significant ($\chi^2 = 1\ 016$ and $2\ 020$ $df = 2$)

Discussion

The better development found in the first born during the first years is in good agreement with the findings of Bayley [3] She found in American children tested from 1–15 months of age that first born compared with others obtained higher scores at 11 ages (of 15) The results may well be due to the fact that parents give greater attention to their first-born.

One reason why the first born are no longer in the lead after the first years may be that by then they have more often got younger siblings. Up to 5 year of age 55% ($n = 46$) of the first-born had got siblings as against 22% ($n = 28$) of the rest

We have calculated the mean difference between the quotients at 1 and 3 years for children who got or who did not get siblings during their first 3 years of life In the first group the quotients fell by an average of 8.3 points In the group without siblings up to 3 years the quotients rose by an average of 2.3 points. The difference between these mean differences is highly significant ($t = 3\ 49$ 0 001) In the same way the mean differences were calculated from 3–5 years for those who got and those who did not get siblings during that period In the group who did not get siblings between their third and fifth year the IQ went up by an average of 0.36 point in the other group it fell by an average of 1.29 points. The difference between these values is not significant ($t = 0\ 72$)

Relation to Conditions of Conception

Our material includes 23 illegitimate children. We have compared this group with the group of legitimate children.

Results

Table 11 shows that there were no significant differences before the age of 5 years, when the difference is clearly significant in favour of the legitimate children At 18 months and 3 years there is a tendency in the same direction.

We have also compared children conceived before with those conceived after marriage At 6 months the children conceived before marriage were significantly more developed than those conceived after marriage From 18 months the tendency is in the opposite direction and at 5 years the difference is highly significant in favour of the children conceived in wedlock (Table 11)

A comparison between illegitimate children and those conceived before but born

in wedlock shows no significant difference up to 3 years. At 5 years the children conceived before marriage have higher quotients than have illegitimate children, the difference being significant at the 0.01 level.

Comments on Interrelations between Social Grouping, Mother's Age, Conditions of Conception, Order of Birth of Child, and Arrival of Younger Siblings

From the preceding pages it will be seen that many variables correlate to the children's mental development. The question arises as to what extent these variables are intermingled.

62.5 % of young mothers' children are first-born. The corresponding figures for the intermediate and older groups are 33 and 17 % respectively.

We do not find significant differences between children of mothers in different age groups until the children are 2 years old. At that age the mean quotients of children of older mothers are significantly lower than those of younger. Most of the children of young mothers are first-born but very few (17 %) of those of older mothers. We know that at 2 years of age first-born children have also significantly higher mean quotients than have other children. But at 3 and 5 years high values are no longer found either among the children of young mothers or among first-born.

By 3 years of age 40 children had got younger siblings, the majority or 62.3 % (n = 31) of them being children of young mothers. The quotients of children who had got siblings before the age of 3 years fell significantly from 1 to 3 years compared with children without younger siblings. It is therefore probable that the decline for children of young mothers from 3 years on is partly due to the advent of siblings. The same may be true of the decline in mean quotients for first born between 2 and 3 years, since to a large extent they are the same children.

The young mothers are significantly more often in the lowest social class. Both for the young mothers and for the lowest social group the quotients are lower than the quotients of the intermediate group of mothers and of higher social classes at 3 and 5 years. Both factors may be of importance.

There is no significant age difference between the mothers of illegitimate and of children conceived before wedlock but both groups are significantly younger than the mothers of those conceived after marriage, as we have seen the quotients of the young mothers' children are significantly lower than those of the intermediate group's children at 3 and 5 years. The difference between those conceived after marriage and the others can thus be related to the difference in age of the mothers. The significant difference at 5 years between the illegitimate and the children conceived before wedlock cannot, however, be explained in this way, because the mean age of the mothers in both groups is around 24 years. It may instead be related to the fact that mothers of illegitimate children belong to the lowest social class more often than do mothers, who have conceived before wedlock but married before the child was born.

Summary

The psychomotor (up to 2 years) and mental development of around 200 children as reflected in the Brunet-Lézine and Terman Merrill tests has been followed from 3 months to 5 years in a longitudinal study

In ratings of language development at 3 and 5 years the only significant difference between first born and others is in enunciation (0.05 level) at 3 years (see Table 6).

Ratings were also made of the children's vocal communicativeness from 1 to 5 years of age on a 5-point scale, 1 representing the lowest and 5 the highest degree of communicativeness. First-born and others were compared by χ^2 testing with respect to rated communicativeness. At 2 and 3 years there is a significant difference between first-born and others (0.005 and 0.02 respectively, $\chi^2 = 12.06$ and 8.788, $df = 2$). Also at 18 months there is a tendency in the same direction (0.10, $\chi^2 = 4.718$, $df = 2$). At these ages the first-born are throughout the most communicative. At one and five years the differences are not significant ($\chi^2 = 1.016$ and 2.029, $df = 2$).

Discussion

The better development found in the first-born during the first years is in good agreement with the findings of Bayley [3]. She found in American children tested from 1–15 months of age that first-born compared with others obtained higher scores at 11 ages (of 15). The results may well be due to the fact that parents give greater attention to their first-born.

One reason why the first born are no longer in the lead after the first years may be that by then they have more often got younger siblings. Up to 5 year of age 55% ($n = 46$) of the first-born had got siblings as against 22% ($n = 28$) of the rest.

We have calculated the mean difference between the quotients at 1 and 3 years for children who got or who did not get siblings during their first 3 years of life. In the first group the quotients fell by an average of 8.3 points; in the group without siblings up to 3 years the quotients rose by an average of 2.3 points. The difference between these mean differences is highly significant ($t = 3.49$, 0.001). In the same way the mean differences were calculated from 3–5 years for those who got and those who did not get siblings during that period. In the group who did not get siblings between their third and fifth year the IQ went up by an average of 0.38 point, in the other group it fell by an average of 1.29 points. The difference between these values is not significant ($t = 0.72$).

Relation to Conditions of Conception

Our material includes 23 illegitimate children. We have compared this group with the group of legitimate children.

Results

Table 11 shows that there were no significant differences before the age of 5 years, when the difference is clearly significant in favour of the legitimate children. At 18 months and 3 years there is a tendency in the same direction.

We have also compared children conceived before with those conceived after marriage. At 6 months the children conceived before marriage were significantly more developed than those conceived after marriage. From 18 months the tendency is in the opposite direction and at 5 years the difference is highly significant in favour of the children conceived in wedlock (Table 11).

A comparison between illegitimate children and those conceived before but born

in wedlock shows no significant difference up to 3 years. At 5 years the children conceived before marriage have higher quotients than have illegitimate children, the difference being significant at the 0 01 level.

Comments on Interrelations between Social Grouping, Mother s Age Conditions of Conception, Order of Birth of Child, and Arrival of Younger Siblings

From the preceding pages it will be seen that many variables correlate to the chil dren s mental development The question arises as to what extent these variables are intermingled.

62.5 % of young mothers' children are first born. The corresponding figures for the intermediate and older groups are 33 and 17 % respectively

We do not find significant differences between children of mothers in different age groups until the children are years old. At that age the mean quotients of children of older mothers are significantly lower than those of younger Most of the children of young mothers are first-born but very few (17 %) of those of older mothers. We know that at years of age first born children have also significantly higher mean quotients than hav other children But at 3 and 5 years high values are no longer found either among the chil dren of young mothers or among first-born.

By 3 years of age 49 children had got younger siblings the majority or 63.3 % (n = 31) of them being children of young mothers. The quotients of children who had got siblings before the age of 3 years fell significantly from 1 t 3 years compared with children without younger siblings. It is therefore probable that the decline for children of young mothers from 3 years on is partly due to the advent of siblings The same may be true of the decline in mean quotients for first-born between 2 and 3 years, since to a large extent they are the same children

The young mothers are significantly more often in the lowest social class Both for the young mothers and for the lowest social group the quotients are lower than the quotients of the intermediate group of mothers and of higher social classes at 3 and 5 years. Both factors may be of importance.

There is no significant age difference between the mothers of illegitimate and of children conceived before wedlock, but both groups are significantly younger than the mothers of those conceived after mar riage as we have seen, the quotients of the young mothers children are significantly lower than those of the intermediate group s children t 3 and 5 years. The difference between those conceived after marriage and the others can thus be related to the difference in age of the mothers The significant difference at 5 years between the illegitimate and the children conceived before wedlock cannot, however be ex plained in this way because the mean age of the mothers in both groups is around 24 years. It may instead be related to the fact that mothers of illegitimate children belong to the lowest social class more often than do mothers, who have conceived before wedlock but married before the child was born.

Summary

The psychomotor (up to years) and mental development of around 200 children as reflected in the Brunet-Lézine and Terman Merrill tests has been followed from 3 months to 5 years in a longitudinal study

The gestational age of the child is found to be related to developmental level during the 9 first months

Pearsson correlations have been calculated. The correlations between proximate ages are of the order of 0 50–0 75 but diminish quickly with increasing time intervals Like most other authors we have found that tests for infants have little long term predictive value for normal children, but that predictability increases with age

Significant differences between the sexes in favour of girls are present from 18 months to 3 years, most marked at 2 years Girls are more advanced particularly in the language and social sphere This difference is not equally distributed over all social classes, a significant difference between the sexes being found principally within the lowest class. There is a tendency in the same direction within the highest class while no significant differences exist within the middle class.

Significant differences in developmental level were found between social classes. Two types of classification were applied, the Swedish and Graffar s system

At 3 and 6 months the mean quotients of the highest social class are low compared with the middle and lowest classes with the Swedish system of social grouping the differences are significant At 9 and 12 months the classes do not differ significantly From 18 months there are significant differences in the opposite direction the highest class having the higher and the lowest the lower mean quotients. At 3 and 5 years the difference is significant at the 0 001 level on the basis both of Swedish and of Graffar s classification

The socio-economic special scales (occupation mother s education, housing income) were related to developmental level up to 5 years of age A positive relation is earliest manifested in respect of the mother s educational level and the family s occupational status (from 18 months). At 3 and 5 years the children with better conditions in all four scales have significantly higher quotients.

From 3 months to 2 years the motor coordination language and social mean quotients in the development test were related to socio-economic total and partial scales. There are no significant differences in any of the quotients for children living in better than in worse housing conditions.

The group of children whose parents have low incomes compared with those of parents with high incomes are significantly forward in particularly coordination ability at 3 and 6 months, and in respect of social and motor development at 3 months.

Children of parents in the high occupational group have significantly higher coordination quotients at 18 and 24 months than have children of parents in the low group In other respects there is no significant relation between subscale quotients and occupational grouping

As regards the mother s educational level there is an almost significant relation with the child s language development from 12 months of age in favour of the more highly educated group This significance level is successively strengthened at 18 and 24 months. A highly significant relation between mother s educational level and child s coordination ability exists also at 18 and 24 months

The child s development level was related to maternal age At 2 years the mean

quotients of the children of young mothers (<25 years) are significantly higher than those of older mothers children (>32 years). At 3 and 5 years the children of medium-aged mothers (26–32 years) have significantly higher quotients than those of young and older mothers.

First born are more developed than second-born during the first 2 years, the differences between the mean quotients of the first born and second born being significant at 6 9 and 24 months. At 2 years the difference is most marked in the language sphere.

No significant differences in mean quotients between legitimate and illegitimate children exist until 5 years of age when the difference is clearly significant in favour of the legitimate ones. Children conceived before marriage were compared with those conceived after marriage the former being significantly more developed at 6 months. As from 18 months the tendency is reversed and at 5 years the difference is clearly significant in favour of children conceived after marriage.

The child s development level was related to the gainful employment of mothers from 1 to 5 years. No significant differences were found at any age between the mean quotients of the children of gainfully employed mothers and others.

Possible interactions between various social and family factors are discussed.

APPENDIX I. *Definitions of language rating variables used at 3 and 5 years.*

Enunciation. Clarity and correctness of enunciation of words used (irrespective of vocabulary and syntax)

1	2	3	4	5
Mostly unintelligible	Difficult to understand owing to many faulty sounds or to pervading tendency to mumble.	Most utterance can be understood but are either not very clearly spoken or subject to three or more pervasive childish faults of enunciation.	Generally clear. One or two pervasive childish faults, or occasional lapses or faulty system of enunciation taken over from adults involving slurred or missing consonants.	Clear correct speech sounds throughout (local variations are acceptable if they do not involve corruption of consonant sounds.)

Maturity of language use. To be judged on length and complexity of sentence formation, on vocabulary in use (not Picture vocab. score) and on success in communicating ideas verbally—irrespective of amount of communication attempted.

1	2	3	4	5
Single words only	Elementary sentences, seldom exceeding 3 words, or few longer utterances interspersed with jargon.	Sentences up to 6 or 7 words. Still some difficulty in making meaning clear or attempts at verbal expression distinctly limited.	Simple sentences which are often incomplete, but adequate for most practical purposes. Or correct constructions but limited vocabulary	Mature, correctly worded sentences with vocabulary in advance of the average.

Comprehension of language. Child's evident understanding of what is said to him, as indicated by his responses both in the test and in general conversation. (Distinguish failure to comprehend *from* lack of interest, refusal to co-operate or poor hearing.)

1	2	3	4	5
No apparent comprehension of the simplest instructions (at 3 years defined by: 'Come here', "Give it to me", or parts of body and Identification by Name Tests)	Below average for age. (at 3 years defined by: Fails one or more tests at Year III or below apparently through lack of comprehension of instructions, e.g. Identification by use, Picture Memory—or the equivalent) in other situations)	Average comprehension for age.	Above average for age (at 3 years defined by: Passes 3 of the following 4 tests at III – 6; Simple commands, Comparison of Sticks, Identification by use, Comprehension of questions—or the equivalent.)	Mature intelligent understanding of what is said.

Material and Methods

The material presented here comprises a sample of 21. children, born during the years 1955–1958 living in Solna, a town near Stockholm. For further information of the composition and representativeness of the sample see papers I and II of this series [13, 14].

The analyses comprise the following variables, sex, birth order of the children, mother age social class, educational level, d elling reasons for weaning given by the mothers nd the attitude to breast-feeding and personality traits of the mothers.

The data regarding feeding are based on nterviews with the mothers at the ages of 1 3 6, 9 1., 18 4 30 nd 48 months. (Form 1 columns 31–58) [6] They comprise detailed information of the type of milk, method of feeding and problems connected ith it

All the dat were collected soon after the particular event had occurred Any advice concerning breast-feeding and weaning was given to the mothers through the usual channels, at the Child Welfare Centres, by private practitioners or other means of information.

Results

The Duration of Breast feeding

The incidence of breast-feeding and the time of weaning in the sample are shown in Table 1 and Fig. 1

Three of the babies were never breast-fed, since two mothers had tuberculosis and one baby could not suck. On the other hand 3 children were breast-fed more than 12½ months; one of them received its last breast-feed at 22 months and one at 3 years and 8 months. In both cases these mothers were in the oldest age group (see Table 2) and had several children.

One half of the mothers weaned their children within 4 months (25th percentile for weaning = 1 25/28 month, 75th per centile = 7 months). (See Fig 1) The data do not signify that the babies were exclusively breast-fed up to the time of weaning Some supplementary formula may have been given.

The Development of Children in a Swedish Urban Community A Prospective Longitudinal Study

V Breast feeding and Weaning Some Social psychological Aspects

by G KLACKENBERG and I KLACKENBERG-LARSSON

Introduction

In the investigations of breast-feeding carried out in Sweden in the 1940s and 1950s by Herlitz [8] Nordenfelt [17] Ström [22] v Sydow [23] Mellander Vahlquist & Mellbin et al [15] it was found throughout that the duration of breast-feeding tended to decrease The same observations are reported from other countries in Western Europe and from the U.S.A e g by Douglas [4] Jackson et al [11], and Westropp [24] In the U.S.A the frequency of children who are exclusively breast-fed on discharge from the maternity hospital has decreased from 38 % in 1946 to 21 % in 1956 [16] whereas in Sweden the corresponding figure in 1950 was nearly 95 % and as recently as 1963 it was 83 % [18 19]

The tendency is evident in the annual reports from the Stockholm Municipal Child Welfare Centres Over the past 10 years (1956–1965) the number of babies exclusively breast fed for 2 months has gradually fallen from 69 % to 53 % for 4 months from 40 % to 30 and for 6 months from 26 % to 16 % [1 2]

The cause of this unmistakable decrease is obscure The reasons have been sought in social psychological and biological factors No unequivocal results can be derived from reports of investigations undertaken to throw light on this question. Most of these studies have been retrospective with consequent uncertainty in assessment Hytten & Thomson [10] stress the difficulties in making comparisons, as in many of these studies incomplete data are given on for instance social class, the mother s age civil status and gainful employment and the child s successional number in the family In a recent investigation Hindley et al [9] compared infant feeding in samples from Brussels London Paris, Zürich and ours from Stockholm studied by similar longitudinal methods These studies are coordinated by the International Children s Centre in Paris. The differences in duration of breast-feeding are great even between countries geographically situated as closely as those included in Hindley's et al study The median ages of weaning vary between 0 92 months in the Brussels sample to 4.5 months in the Stockholm sample

As the breast feeding is more common and continues longer in the Swedish group of mothers than it does in any of the corresponding growth-study groups it may be of value to analyse further and separately some social and family factors in association with breast feeding

V Breast feeding and Weaning Some Social psychological Aspects

by G KLACKENBERG and I KLACKENBERG-LARSSON

Introduction

In the investigations of breast-feeding carried out in Sweden in the 1940s and 1950s by Herlitz [8] Nordenfelt [17] Ström [22] v Sydow [23] Mellander Vahlquist & Mellbin *et al* [15] it was found throughout that the duration of breast-feeding tended to decrease The same observations are reported from other countries in Western Europe and from the U.S.A e.g by Douglas [4] Jackson *et al.* [11] and Westropp [24] In the U.S.A. the frequency of children who are exclusively breast-fed on discharge from the maternity hospital has decreased from 38 % in 1946 to 21 % in 1956 [16] whereas in Sweden the corresponding figure in 1956 was nearly 95 % and as recently as 1963 it was 83 % [18 19]

The tendency is evident in the annual reports from the Stockholm Municipal Child Welfare Centres. Over the past 10 years (1956–1965) the number of babies exclusively breast-fed for 2 months has gradually fallen from 69 % to 53 % for 4 months from 40 % to 30 % and for 6 months from 26 % to 16 % [1 2]

The cause of this unmistakable decrease is obscure The reasons have been sought in social psychological and biological factors. No unequivocal results can be derived from reports of investigations undertaken to throw light on this question. Most of these studies have been retrospective with consequent uncertainty in assessment Hytten & Thomson [10] stress the difficulties in making comparisons as in many of these studies incomplete data are given on, for instance social class, the mother s age civil status and gainful employment and the child s successional number in the family In a recent investigation Hindley *et al* [9] compared infant-feeding in samples from Brussels London Paris, Zürich and ours from Stockholm studied by similar longitudinal methods. These studies are coordinated by the International Children s Centre in Paris The differences in duration of breast-feeding are great even between countries geographically situated as closely as those included in Hindley s *et al* study The median ages of weaning vary between 0 02 months in the Brussels sample to 4.5 months in the Stockholm sample

As the breast-feeding is more common and continues longer in the Swedish group of mothers than it does in any of the corresponding growth study groups, it may be of value to analyse further and separately some social and family factors in association with breast feeding

secondary school, junior and senior stage or an academic degree continue breast feeding significantly longer than do mothers with only elementary school education.

Since the tested variables may be more or less related χ^2-analyses were carried out with the material divided into subgroups. The variable of the child ordinal position has been excluded as it lacked influence in the whole material. The results are shown in Table 3 and the following conclusions may be drawn.

Sex The fact that boys are breast-fed longer than girls is most marked in the mothers of the higher age-group and in the mothers with higher education. The combined χ^2 values within these variables are significant at the 0.05 level. A tendency in the same direction is also seen in social classes I + II + III.

Age The tendency for young mothers to

Relationship between weaning and various family and social data

In analysing the data (by the χ^2 method) the sample has been dichotomized near to the median value for duration of breast-feeding Mothers who have given the last breast-feed at 4 months or earlier are referred to the category of earlyweaners and the others to lateweaners

Table 2 shows the relation to sex birth order of the children mother s age social class educational level and dwelling There is a sex difference the boys being breast fed longer than the girls ($p < 0\,02$) but no difference in relation to birth order With the mothers divided into 3 age-groups, 25 years or younger 26–32 years and 33 years or more only the difference between the youngest and the intermediate age-group (or the two oldest age-groups) is significant ($p < 0\,005$) As regards the social grouping by Graffar s system the mothers in social class I + II continue breast-feeding longer than the mothers do in social classes III and IV + V The difference is significant at the 0 001 level between I + II and IV + V and at the 0 01 level between I + II and III

Mothers with the higher education

U.S.A a shift is reported [3] from earlier longer breast-feeding periods in low socio-economic groups to longer period for middle class Contradictory results have been obtained in England [0] The results reported from Belgium [20] and Sweden [17] agree with ours, namely a long duration of breast-feeding in the highest social class.

Mothers Reasons for Weaning

The mothers were asked about their reasons for weaning For mothers, who weaned their children before or at 6 months, the predominating reason was "no or insufficient milk In about one-third this was the only reason given. No or insufficient milk together with the child s refusal to take the breast or preference for other milk was the most common combination Tiredness and nervousness, etc were the reasons in just over one-fourth of the 127 mothers; medical obstacles to breast feeding, such as sore or inflamed nipples, play a relatively minor role and were st ted only by mothers who weaned their babies in the first two month

As regards gainful employment as a reason for weaning it is evident that the desire to resume work or to start working plays no mport nt role in the falling in cidence f breast feeding This will be seen from the mere fact that 6 (full time) of the mother our sample were gainfully employed t the time (4 months), hen 50 of the children had been eaned Only 3 f the mothers gave g inful employment a reason.

(onmeall

The complexity of the factors of psychic nd physiological nature involved in breast-feeding makes it difficult to analyse the variables influencing weaning We are concerned here with processes that are *only in part* controlled by the conscious will of the mothers. It may therefore be questioned to what extent the mothers answers to direct inquiries of this nature would supply complete information about the reasons for weaning Furthermore a mother who does not breast-feed her baby for the length of time advised by the Child Welfare Centres, would presumably be inclined to feel guilty especially if she gives up breast-feeding for reasons that are not regarded as acceptable

In more primitive societies the duration of breast-feeding is considerably longer [25]; the falling frequency of breast-feeding seems mostly t be a phenomenon of Western civilization. This continuous process has been faster in some Western countries than in others.

The Mothe s Attitude to Breast feeding and to Weaning

During the period of breast feeding the interviewer asked the mothers how they liked it The answers were graded as positive indifferent and negative" The statement that the breast-feeding made them tired was also in luded among the nswers

Judged by their statements most of the mothers had a positive attitude to breast feeding both t the 1 month (69 %) and at the 3-month (77 %) interview The greater percentage of mothers who at the later interview stated that they liked breast-feeding is related to the fact that the majority (8 of 1°) of those with a negative attitude *at 1 month had* stopped weaning before 3 months.

stop breast-feeding earlier than the others is seen in all the subgroups (when calculated separately) with the exception of Graffar's lowest social class The combined χ^2 values within the three variables sex, social class and mother's education are all significant at least at the 0 02 level

Social class The differences between social classes are most prominent among boys and among the intermediate and older groups of mothers. The combined χ^2 values within the variables sex and mother's age are both significant at least at the 0 01 level for the difference between classes I+II versus IV+V and at least at the 0 05 level for the difference between classes I+II versus III

Education. The significance levels for the differences between the mothers in the two educational groups are valid only for the boys and the intermediate and older groups of mothers The combined χ^2 values within the variables sex and mother's age are both significant at the 0 05 level

Dwelling Overcrowding (≥ 2 persons per room) is most common in the lower social classes These include more young mothers in our sample There is no significant difference in the duration of breast feeding between the overcrowded group at a lower social level (Graffar social score 13–20 lowest category) neither for young nor for older mothers A comparison within social score 13–20 between mothers in modern flats (hot and cold water w c bathroom) and those in old fashioned flats shows however a significant difference at the 0 02 level between the groups ($\chi^2 = 6.39$) Those who live in old fashioned houses wean their children earlier

Comments

The results of the different analyses (Tables 2 and 3) can be summarized as follows. The duration of breast feeding is found to be related to each of the factors sex mother's age and social class. The boys, the children of medium and older mothers and the children in the highest social class are breast fed longest Mothers with higher educational level and mothers (in social score 13–20) living in modern flats breast feed their children longer than do others —No relation to birth order was found

Nordenfelt [17] in his investigation of materials from the Child Welfare Centres in Stockholm reported that the first-born were breast-fed longer Herlitz [8] found no significant differences but a tendency in the opposite direction Both studies however include only married mothers. Moreover as Nordenfelt excluded those who are gainfully employed their investigations are not fully comparable with ours. Dykes [5] states that family size has little influence on the duration of breast feeding which is in accordance with our findings. His investigation comprised all children ($n = 1403$) born in 1945 in a town in England

The observation that young mothers breast feed for a shorter time has earlier been made in some comprehensive Swedish investigations by Herlitz and Nordenfelt [8 17] This relation to mother's age however does not seem to be generally found in other countries [9]

The relation to social class seems by no means to be a simple one different results have been reported from different countries and at different periods of time From the

U.S.A a shift is reported [3] from earlier longer breast-feeding periods in low socio-economic groups to longer period for middle class. Contradictory results have been obtained in England [9] The results reported from Belgium [20] and Sweden [17] agree with ours namely a long duration of breast-feeding in the highest social class.

Mothers Reasons for Weaning

The mothers were asked about their reasons for weaning. For mothers who weaned their children before or at 6 months, the predominating reason was "no or insufficient milk In about one-third this was the only reason given. "No or insufficient milk together with the child s refusal to take the breast or preference for other milk was the most common combination "Tiredness and nervousness, etc were the reasons in just over one fourth of the 1*7 mothers medical obstacles to breast feeding, such as sore or inflamed nipples play a relatively minor role and were stated only by mothers who weaned their babies n the first two months

As regards gainful employment as a reason for weaning it is evident that the desire to resume work or to start working plays no important role in the falling incidence of breast feeding. This will be seen from the mere fact that 6 (full-time) of the mother in our sample were gainfully employed t the t me (4 month) when 50 of the children had been weaned Only 3 of the mothers gave gainful employment as a reason

Comment

The complexity of the factors of psychic nd physiological nature involved in breast-feeding makes it difficult to analyse the variables influencing weaning We are concerned here with processes that are only in part controlled by the conscious will of th mothers It may therefore be questioned to what extent the mothers answers to direct inquiries of this nature would supply complete information about the reasons for weaning Furthermore a mother who does not breast-feed her baby for the length of time advised by the Child Welfare Centres would presumably be inclined to feel guilty especially if she gives up breast feeding for reasons that are not regarded as acceptable

In more primitive societies the duration of breast-feeding is considerably longer [.5], the falling frequency of breast-feeding seems mostly to be a phenomenon of Western civilization. This continuous process has been faster in some Western countries than in others.

The Mother s Attitude to Breast-feeding and to Wean ng

During the period of breast feeding the interviewer asked the mothers how they liked it The answers were graded as positive indifferent' and negative The statement that the breast-feeding made them tired was also included among the answers

Judged by their statements most of the mothers had a positive attitude to breast-feeding, both at the 1 month (69 %) and t the 3-month (77 .) interview The greater percentage of mothers who at the later interview stated that they liked breast feeding is related to the fact that the majority (8 of 1*) of those with a negative attitude at 1 month had stopped weaning before 3 months.

Very few mothers show persistently an indifferent or negative attitude There are many variants of the answers in the positive group such as restful delightful the best time of the day relaxing But the pleasure in breast-feeding is no guarantee against early weaning even though it would be expected to signify a more favourable prospect than the sufferings that some mothers describe such as giddiness headache waste of time nervousness pain and extraordinary tiredness An analysis of the total sample for a possible relation between time of weaning and declared attitude to breast-feeding at 1 month did not however give any significant results

When the breast feeding period was over the mothers were asked whether they felt relieved. The answers were classified as follows Did not like to stop breast-feeding indifferent ambivalent relieved.

The mothers reactions to the fact that the breast-feeding period had come to an end were fairly similar in those who weaned their children before and after 6 months About half (50 % and 54 %, respectively) were pleased with the situation They felt relieved and were glad that the breast-feeding period was over In some cases words such as tiring and wearisome accompanied the answers as an explanation On the other hand about one fourth (27 % and 22 %, respectively) of the early weaning and the late-weaning group did not like to stop breast feeding Some expressed regret a feeling of having lost something that was valuable of not having the baby to themselves as much as before The most likely interpretation of the fact that so many of the mothers who had continued breast feeding for at least 6 months did not feel relieved at the time of the last breast-feed might be that to those mothers breast-feeding was a pleasure rather than a duty

Comments

It may be questioned how far the mothers answers express what they really feel and not what they think one should feel if one wants to be regarded as a good mother The interviewer often felt that the positive answers to breast-feeding were given without any great enthusiasm It may seem somewhat odd that so many positive breast-feeders felt cessation as a relief

Duration of Breast feeding and Weaning Troubles

The mothers were asked about the child s response to weaning The answers were divided into three groups by the degree of weaning difficulty and graded as difficult moderate and easy" The duration of breast feeding dichotomized at 4 months was analysed in relation to the degree of difficulty in weaning using the χ^2 test The answers difficult" and moderate were brought together into one group versus the easy group

The children who were difficult to wean were those who were breast-fed longest The difference is significant at the 0 01 level ($\chi^2 = 8\ 08$)

When calculated for boys only the difference is still significant at the 0 01 level (χ^2 8 40) but for the girls alone it is not significant (χ^2 0 01)

Comments

The fact that weaning at a later time is regarded as more difficult may be related

TABLE 4 *Ratings of personality variables and duration of breast feeding*

Duration of breast feeding	Self-confidence		Security		Orderliness		Temperament	
	1+2	3–5	1+2	3–5	1+2	3–5	1+2	4+5
3 mos. or shorter	7	[illegible]	8	[illegible]	20	56	25	16
6 mos. or longer	29	[illegible]	23	[illegible]	45	49	22	37
χ^2	10.88		5.48		8.27		10.78	
p	$< .001$		$< .02$		$< .01$		$< .005$	

to the fact that the habit of sucking has become more deep-rooted and then is more difficult to terminate.

That this relation only holds true for the boys is perhaps related to the tendency of the mothers to breast feed the boys longer

Duration of Breast feeding and Mother's Personality

At each interview the psychologist tried to rate some traits of the mother's personality on 5-point scales. The ratings of the mothers who had breast fed their babies for the first 3 months were compared with those who had continued for at least up to 6 months. We used the rating scale units which were most common for a mother during the first 2 years. The mothers who were rated equally often as e.g. points 2 and 3 were randomly distributed between 2 and 3

The rated variables were self-confidence, security, orderliness and temperament. The scale unit for self-confidence range from "highly self-confident" (1) to "diffident" (5). Mothers rated as having great or fairly great self-confidence (1+2) were compared with the others. For the variable "orderliness" the scale unit range from "pedantic" (1) to "careless" (5). Those rated "pedantic" and "orderly" were brought together into one group which was compared with the others. As regards the variable "temperament" those rated as "quick tempered" and "lively" (1+2) were compared with those rated as "calm" and "slow" (4+5).

Table 4 shows the distributions, χ^2 and p-values

Comments

The mothers who had continued breast-feeding for 6 months or longer have more often been rated as more self-confident, secure, orderly and calm. It is perhaps not surprising that mothers with these qualities breast feed longer than others.

Night feeds in Infancy

According to the principles in the maternity wards the infants are not given night-meals. The children of the sample were born in different maternity hospitals and in none of the cases do the collected data indicate that they were treated differently in this respect from newborn babies in general. The picture changes after the return home from the hospital. Fig. 4 shows the percentage of infants who were given night meals at various ages, that is, who were fed (at the breast or from a bottle) some time between midnight and

Very few mothers show persistently an indifferent or negative attitude There are many variants of the answers in the positive group such as restful delightful the best time of the day relaxing" But the pleasure in breast-feeding is no guarantee against early weaning even though it would be expected to signify a more favourable prospect than the sufferings that some mothers describe such as giddiness headache waste of time nervousness pain and extraordinary tiredness . An analysis of the total sample for a possible relation between time of weaning and declared attitude to breast feeding at 1 month did not however give any significant results

When the breast-feeding period was over the mothers were asked whether they felt relieved The answers were classified as follows: Did not like to stop breast-feeding *indifferent* ambivalent, relieved.

The mothers reactions to the fact that the breast-feeding period had come to an end were fairly similar in those who weaned their children before and after 6 months About half (50 % and 54 %, respectively) were pleased with the situation They felt relieved and were glad that the breast feeding period was over In some cases words such as tiring and wearisome accompanied the answers as *an explanation On the other hand* about one-fourth (27 % and 22 % respectively) of the early weaning and the late-weaning group did not like to stop breast feeding Some expressed regret a *feeling of having* lost something that was valuable of not having the baby to themselves as much as before The most likely interpretation of the fact that so many of the mothers who had continued breast feeding for at least 6 months did not feel relieved at the time of the last breast feed might be that to these mothers breast feeding was a pleasure rather than a duty

Comments

It may be questioned how *far the mothers* answers express what they really feel and not what they think one should feel if one wants to be regarded as a good mother The interviewer often felt that the positive answers to breast-feeding were given without any great enthusiasm It may seem somewhat odd that so many positive breast feeders felt cessation as a relief

Duration of Breast feeding and Weaning Troubles

The mothers were asked about the child s response to weaning The answers were divided *into three groups* by the degree of weaning difficulty and graded as difficult moderate and easy" The duration of breast feeding dichotomized at 4 months was analysed in relation to the degree of difficulty in weaning using the χ^2 test The answers difficult and moderate were brought together into one group versus the "easy group.

The children who were difficult to wean were those who were breast fed longest The difference is significant at the 0 01 level ($\chi^2 = 8\ 98$)

When calculated for boys only the difference is still significant at the 0 01 level ($\chi^2 = 8\ 46$) but for the girls alone it i not significant (χ^2 0 01)

Comments

The fact that weaning at a later time is regarded as more difficult may be related

analysed for their association with various social and family factors and personality variables in the mothers. The following statistically significant relationships were found 1 Boys are breast-fed longer than girls. 2. Mothers in the higher age-group (26 and over) continue breast-feeding longer than do younger mothers (under 26). 3 Mothers of the highest social class (Graffar I + II) continue breast feeding longer than do mothers in the intermediate (Graffar III) and the lowest (Graffar IV + V) social classes. 4. Mothers with higher education continue breast-feeding longer than do mothers with only elementary school education. 5 In the lowest social class mothers who live in old-fashioned houses stop breast feeding earlier than do mothers living in modern houses. 6. Some personality traits of the mother are more often than others associated with long-continued breast-feeding

No statistical relationships were demonstrated between the duration of breast feeding and overcrowding or the child's successional number in the family

The reasons for weaning were analysed "No or insufficient milk" was the most common reason given by mothers who weaned their babies before 6 months Gainful employment was of very little importance as a reason for weaning.

The mothers attitudes towards breast-feeding in the child's first and third months of life were generally positive. The duration of breast-feeding cannot be predicted from the attitude declared by the mothers.

The frequency of night-feeding on the return home from the maternity hospital was 85 % and at 3 months 25 %. The boys received night meals for a significantly longer period than did the girls. The mother's age, the child's successional number in the family social class, the duration of breast feeding and the mother's attitude to breast-feeding showed no association with the continuation of night-feeding.

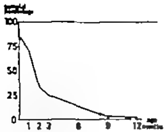

Fig 2. Night meal cessation (n = 212).

5 o clock a m It will be seen that 85 % of the babies received night-meals

Information about the time of cessation of night-feeding was obtained from the mothers at the interviews following her return home In some cases night-feeding started later than the first month of life or ceased for a time to begin again later As a rule however it was continued fairly uniformly (with a shift towards early morning) up to the time when there was no longer any need for it and the child began to sleep through. In other cases the child could wake once or a few times a week during the transitional stage This was usually accepted by the mother as an expression of the child s need of a feed More or less successful attempts to avoid feeding the baby in the night were reported by some mothers Fear of disturbing the rest of the family and the neighbours was in some cases stated to be the reason for keeping the child quiet by a night-feed.

Seventy five per cent of the children had finished their night-mealperiod at the age of 3 months The group of 60 children who had never got a night-meal or had had the last one at or before the age of 1 month was compared in various respects with those 50 children who had retained the habit of having night feeds for more than 3 months The comparison concerned the association between night feeding and the child s sex the mother s age the child s successional number in the family (first child versus others) social class (as defined in Sweden) and the duration of breast-feeding (longer or shorter than 4 months) The two groups compared differed only with respect to the association with the child s sex 36 % (n = 44) of all the boys belonged to the group with night feeds for more than 3 months. The corresponding figures for the girls were 16 (n = 14) The percentage difference is 20 ± 6.3 significant at the 0 001 level

Comments

The sex difference found admits of different interpretations of a speculative nature It may be thought to be associated with more activity together with greater need of nourishment in the boys. But differences in caloric requirements between boys and girls of this age are not known. The basal metabolism in relation to body size shows no difference between the sexes [12] If the differences found can not be assigned to the child s biological characteristics the continued practice of night feeding could be associated with the mothers attitudes to boys. The mothers may be thought to have more positive attitude to them than to girls. Conscious as well as unconscious desires may play a part

Summary

Data on breast-feeding weaning and the practice of giving night meals, collected in the prospective longitudinal growth study presented earlier have been

analysed for their association with various social and family factors and personality variables in the mothers. The following statistically significant relationships were found. 1 Boys are breast fed longer than girls. 2. Mothers in the higher age-group (26 and over) continue breast-feeding longer than do younger mothers (under 26). 3 Mothers of the highest social class (Graffar I+II) continue breast-feeding longer than do mothers in the intermediate (Graffar III) and the lowest (Graffar IV+V) social classes. 4. Mothers with higher education continue breast-feeding longer than do mothers with only elementary school education 5 In the lowest social class, mothers who live in old fashioned houses stop breast-feeding earlier than do mothers living in modern houses. 6 Some personality traits of the mother are more often than others associated with long-continued breast-feeding

No statistical relationships were demonstrated between the duration of breast feeding and overcrowding or the child successional number in the family

The reasons for weaning were analysed "No or insufficient milk" was the most common reason given by mothers who weaned their babies before 3 months. Gainful employment was of very little importance as a reason for weaning

The mothers attitudes towards breast-feeding in the child first and third months of life were generally positive The duration of breast-feeding cannot be predicted from the attitude declared by the mothers

The frequency of night-feeding on the return home from the maternity hospital was 85 % and at 3 months 25 %. The boys received night meals for a significantly longer period than did the girls The mother s age, the child s successional number in the family social class, the duration of breast-feeding and the mother s attitude to breast-feeding showed no association with the continuation of night-feeding

Acta Pædiatrica Scandinavica Suppl. 187 105–121 1968

The Development of Children in a Swedish Urban Community A Prospective Longitudinal Study

VI The Sleep Behaviour of Children up to Three Years of Age

by G KLACKENBERG

Introduction

The sample comprises 12 children, followed from birth onwards. Concerning the course of the study up to the time children are 3 years of age the reader is referred to the general introduction, given in paper I of this series [9].

The results reported here relate to the length of sleep at different times during the children first 3 years of life and to sleep disturbances during the same period.

The data are based on the mother's observations By the standardized interviews information was obtained of the child's sleep not only at the visit but also in the intervals between the visits The values thus attained can therefore form the basis for a cross-sectional analysis and also for long range view of the sleep behaviour of the individual children. In a cross-sectional analysis an occasional waking in the night for example will in the statistical calculations carry the same weight as persistent wakefulness It is only by the longitudinal analysis that the habitual sleep-behaviour of the individual subjects will emerge By recording the event soon after it occurred, the prospective longitudinal method gives smaller margins of error than do retrospective studies [14].

The information obtained concerning sleep will be seen in interview form part II, columns 47–78 [3]. The first two questions are of introductory type their aim being to find out, in general terms, what the mother thinks of the child's sleep and how the sleep disturbances, if any manifest themselves. The next six questions concern bedtime waking time length of sleep, number of day time naps and their duration, and whether these factors show any regularity The next 18 questions relate to the child's behaviour at bedtime, during the first few evening hours, and in the night These inquiries also include the measures taken by the parents in case of trouble. The rest of the questions concern the child's sleeping conditions, such as the bed, bedroom etc

These provided a basis for a numerical description of data and, in the treatment of several items, statistical analysis as well. The latter comprised, in particular prediction and correlation with other data of social somatic, or psychic nature [3 6].

The account will be divided into four main sections.

The Development of Children in a Swedish Urban Community A Prospective Longitudinal Study

VI The Sleep Behaviour of Children up to Three Years of Age

by G KLACKENBERG

Introduction

The sample comprises 212 children, followed from birth onwards. Concerning the course of the study up to the time children are 3 years of age the reader is referred to the general introduction, given in paper I of this series [9]

The results reported here relate to the length of sleep at different times during the children's first 3 years of life and to sleep disturbances during the same period.

The data are based on the mother's observations. By the standardized interviews information was obtained of the child's sleep not only at the visit but also in the intervals between the visits The values thus attained can therefore form the basis for a cross-sectional analysis and also for a long-range view of the sleep behaviour of the individual children In a cross-sectional analysis an occasional waking in the night, for example will in the statistical calculations carry the same weight as persistent wakefulness It is only by the longitudinal analyses that the habitual sleep-behaviour of the individual subjects will emerge By recording the event soon after it occurred, the prospective longitudinal method gives smaller margins of error than do retrospective studies [14]

The information obtained concerning sleep will be seen in interview-form part II, columns 47-78 [3] The first two questions are of introductory type their aim being to find out, in general terms, what the mother thinks of the child's sleep and how the sleep disturbances, if any manifest themselves The next six questions concern bedtime, waking time, length of sleep number of day time naps and their duration, and whether these factors show any regularity The next 18 questions relate to the child's behaviour at bedtime during the first few evening hours, and in the night These inquiries also include the measures taken by the parents in case of trouble The rest of the questions concern the child's sleeping conditions, such as the bed, bedroom, etc.

These provided a basis for a numerical description of data and, in the treatment of several items, statistical analysis as well. The latter comprised, in particular prediction and correlation with other data of social, somatic, or psychic nature [3 6]

The account will be divided into four main sections.

TABLE 1 *The mothers opinion of the children s sleep at various ages in general terms Percentage distribution*

Age (months)	1 (n = 162)	3 (n = 187)	6 (n = 197)	9 (n = [illegible]01)	12 (n = [illegible]08)	[illegible] (n = 194)	4 (n = [illegible]04)	36 (n = [illegible]06)

(b) Evening wakefulness
(c) Night waking
IV Night disturbances during long periods

I The Mother s General Opinion of the Child s Sleep

The answers to the introductory question concerning the mother s general opinion of how the child sleeps were graded as extremely well very well fairly well and not well Table 1 giving the percentage distribution of the answers shows to what extent the mothers find their children s sleep good or not good at different ages. It is a total impression of both day and night sleep including duration of sleep waking and troubles of various kinds.

In Fig 1 the percentage distribution of the gradings that have negative signs (not well and fairly well) is plotted against age separately and taken together At the age of around 3 months the children s sleep behaviour evidently deviates least and at 12–18 months most from the ideal of a long and unbroken sleep [13] At some ages, this curve does not correspond to the true incidence of night waking (cf Fig 6 page 115) As for the one month-old children, most mothers apparently consider it quite natural for the children to wake up in the night (75% have night feeds, cf [11]) and do not always regard this as bad sleep The wakefulness is accepted as part of the sleep pattern at this age. Another deviation from the true frequency of night waking is found at 3 years Many of the children will then wake because of an urge to pass water and/or because they wish to get into the parents beds. This is in many cases not regarded as bad sleep. It is presumably the degree of inconvenience experienced by the mother that determines if she will feel the awakening as a sleep disturbance A break or an interruption of the child s sleep is not always

TABLE 2 *Main groups of complaints on sleep behaviour as a percentage of complaints at four different ages*

Age (months)	3	9	18	36
Night waking	[illegible]	44	63	[illegible]
Poor day sleep	38	28	2	0
Evening wakefulness	0	17	18	28
Resistance to bedtime preparations	0		12	30
Various (light restlessness, night terrors)	0	9	10	14

recognized as a sleep disturbance from the family's point of view: the terms are not always identical. The tolerance of the mothers can also vary according to their personal make-up. These considerations should be borne in mind for the detailed study of the sleep behaviour that will be presented in a subsequent section.

The troubles that the mothers have with their children s sleep vary somewhat with respect to nature and content from time to time. This is best illustrated by Table .., which shows the frequency of the main groups of complaints at four different ages (3 9 18 and 36 months)

Night waking is the predominating complaint about the child's sleep. But for the first year of lif a strikingly large group of mothers are of the opinion that the children sleep too little in the daytime. Resistance to bedtime preparations as well as waking after a short spell of sleep become increasingly common with increasing age and re t 3 years as great a cause of worry as is the night waking.

II Duration of Sleep

Total length of sleep per 4 hours The assessment of the children s total length of sleep per 24 hours is based on a detailed questionnaire and, with the aid of the stated bedtimes and awakening times, the replies provide a value for the length of sleep at different ages.

Fig. * shows the bedtimes and awakening times at 1 * and 3 years. Great individual variations are seen at all age-levels. Some children fall asleep habitually at 6 p.m whereas others are not ready for their night s sleep until 10 o clock. Similarly the within-group variation in the awakening time ranges over a period of 4 hours The children who go to sleep early are not always found among the early wakers, and vice versa although the cumulative percentage curves for the group run a strikingly similar course. At each age-level, there are in fact big differences for the length of sleep with the highest

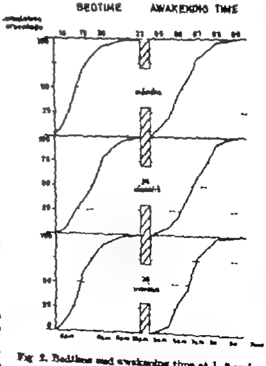

Fig 2. Bedtime and awakening time at 1 2 and 3 years of age.

standard deviations at 6 months of age as shown in Table 3 and Fig 3

The figures in Table 3 refer to the average number of sleep hours per day and per night as well as totally We are concerned here with sleep hours as far as the parents could tell that the child was asleep If the child lies awake in the night the number of sleeping hours was reduced by the lying awake time Numerical values for the length of sleep from the observations at 1 and 3 months were not included The reason for this omission is that it is often extremely difficult to make a sharp definition between sleep and wakefulness in the child's first few months of life. At times the children often lie half asleep and an attempt at condensing the information supplied by the mothers into average values for this age level would imply a seeming exactness. Sources of error of such a gross nature have been avoided.

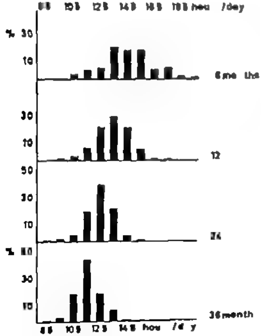

Fig 3. Total sleep in hours/day at different ages.

That the total length of sleep decreases with age is a well known fact During the period 6 months–3 years the decrease of the 24-hour sleep averages about 2½ hours This reduction of the total length of sleep does not depend upon a decrease of the length of the night sleep which varies only slightly but upon a decrease of the length of day sleep For further analysis of the relationships between day and night sleep the reader is referred to a later section of this paper (cf pages 110–111)

Relation between the length of sleep at

different ages in the same child To find out whether the length of sleep of a particular child would provide any forehand information as to the length of his sleep at a later age, the correlation between length of sleep at different ages in the same child was calculated. The results are set out in Table 4

There are correlations, most of them not due to chance between the length of sleep at different ages during the period 6 months–36 months. The correlations are however of a low degree. Accordingly the possibilities to predict the later total length of sleep of a particular child from an earlier observation are small.

Relation of length of sleep to season. To find out whether there are any seasonal variations in the length of sleep, the correlation between the total sleep and the average number of day light hours in the months of the year was calculated for the different age-levels. As the children were observed on, shortly before or after their birthdays, this correlation could be studied for the length of sleep at 12 24 and 36 months There was no significant relationship. The correlation coefficients for the respective ages were − 04 12 and .09 (cf. also page 111 concerning relation of night-sleep t season)

Length of sleep and living space The analysis concerns differences in length of sleep between children t 1 year under different d elling conditions. A division was made into short sleepers (9–13 hours) and long sleepers (15–20 hours) representing two groups of the same size distributed around the mean. "Over crowding' denotes that the family's living space allows as a maximum half a room per person As an example may be mentioned that the most common accommodation that refers the studied families to the category of overcrowded" consists of one room plus a kitchen (the kitchen is counted as a room if large enough to be used for meals and for sleeping purposes) for two parents and two children, that is, four persons. The object of the analysis was to find out whether disturbances from the environment due to overcrowding might reduce the effective sleeping hours. No difference in this respect was found for the children at 1 year of age The χ^2 value was 0.055

TABLE 4 *Correlation coefficients of length of sleep at different ages*

Age (months)	9	12	18	24	36

differ significantly from that of the children whose mothers did not go out to work ($\chi^2 = 2\ 360$) ('long-sleepers' versus 'short-sleepers' cf above)

Relation of length of sleep to mental development quotient The correlations between the children's total length of sleep and the developmental quotient obtained by Brunet-Lezine's development test at each interview are shown in Table 5 At 36 months the Terman–Merrill intelligence test was used It will be seen that a weak negative correlation exists only at 6 months At the other tested age-levels the connection can be neglected.

Day sleep–night sleep Day sleep is here defined as the sleep that occurs after the family and the child have awakened in the morning and up to the time usually between 5 and 7 o'clock in the evening when the child goes to sleep for a longer stretch. In general it was easy to apply this definition when the children had reached the age of 6 months But even after 6 months it seemed in some cases uncertain whether the sleep periods in the afternoon and early evening were to be counted as day or night sleep For example a child who sleeps from 4 to 7 p m but then stays awake for several hours to enter his longest stretch of sleep after say 10 p.m was considered to "settle for the night" at the latter hour On the other hand in the case of a child who having settled at 6 p m. wakes up for his evening meal at 10 p.m and then goes to sleep again the child's night sleep was counted as from 6 p m This problem of definition does not of course affect the total length of sleep discussed in previous sections, but will be of significance in the study of changes in the day sleep and the night sleep respectively

Earlier studies [1 2 4 7 12] have shown that the infant's sleep periods during the first few weeks of life are more evenly distributed over the twice-round-the-clock period. A distinct day–night rhythm cannot be discerned. The change over to a 24-hour pattern with longer night and shorter daytime periods of sleep occurs gradually According to Hellbrügge [8], a typical day–night pattern can be observed at the age of 4 weeks, but not until the end of the first year of life can it be considered to be fully developed. Because of the irregularities during the first months of life it has proved difficult by the methods used in this study to obtain accurate values from the ages of 1 month and 3 months. For this reason the data reported below refer to the observations at 6 months and subsequent interviews up to 36 months

Means and standard deviations for the number of hours of day sleep can be seen in Table 3 (page 108) These hours are distributed among the number of sleep periods set out in Table 6 (for the ages 6 12 24 and 36 months)

The need of a nap in the daytime seldom disappears suddenly from one day to another The break-off is usually preceded

TABLE 6. *Percentage distribution of sleep periods in the day at different ages*

Number of sleep periods in the day	Age (months)			
	9	[illegible]	24	36
0	[illegible]	0 5	21	77
1	8	55	[illegible]	23
2	40	41	1	0

24	198	−.37	< .001
36	168	−.33	<.001

by a period of vacillation between having a nap in the daytime and going to sleep earlier in the evening.

The age at which day sleep is abandoned varies individually Most of the children in the sample passed through this stage between the ages of 2 and 3 years. Among the three-year-old, only 23% has a nap during daytime.

Relation between length of day sleep and length of night sleep It will be seen from Table 7 that there is a correlation between the length of day sleep and the length of night sleep at different ages.

The tendency that can be discovered from Table 7 may be summarized as follows: As the child curtails its sleep by day it lengthens its period of continuous night sleep correspondingly As can be seen, the correlations are not due to chance. They become stronger when the child reaches the age of 2–3 years.

Relation between the length of night sleep at different ages in the same child This analysis is based on the presumption that the children gradually develop a certain sleep pattern—in this case with respect to night sleep—which remains a characteristic A child that at a certain age sleeps for relatively long time in the night may provided that the presumption is correct be expected to have the same relative need of sleep at a later age This analysis therefore concerns the predictability as regards the length of night sleep

Evidently in the nine-month-old the night sleep has not yet reached the stability which affords a meaningful association with later ages (table 8). From the age of 12 months there are significant correlations to the following ages concerning the night sleep

Relation of night sleep to season. In a similar way as concerning seasonal influences on the total sleep duration (cf. page 109) the correlation coefficients of the night-sleep hours and the average of daylight hours were computed. The coefficients indicate that the children slept shorter in the summer nights at 2 and 3 years of age but the negative correlation

36	203	08	—

differ significantly from that of the children whose mothers did not go out to work ($\chi^2 = 2.360$) ('long-sleepers' versus 'short-sleepers' cf. above)

Relation of length of sleep to mental development quotient The correlations between the children's total length of sleep and the developmental quotient obtained by Brunet-Lezine's development test at each interview are shown in Table 5 At 36 months the Terman-Merrill intelligence test was used. It will be seen that a weak *negative correlation exists only at 6* months At the other tested age-levels the connection can be neglected.

Day sleep–night sleep Day sleep is here defined as the sleep that occurs after the family and the child have awakened in the morning and up to the time usually between 5 and 7 o clock in the evening when the child goes to sleep for a longer stretch In general, it was easy to apply this definition when the children had reached the age of 6 months. But even after 6 months it seemed in some cases uncertain whether the sleep periods in the afternoon and early evening were to be counted as day or night sleep For example a child who sleeps from 4 to 7 p m but then stays awake for several hours to enter his longest stretch of sleep after say 10 p m was considered to settle for the night at the latter hour On the other hand, in the case of a child who having settled at 6 p.m wakes up for his evening meal at 10 p.m and then goes to sleep again, the child's night sleep was counted as from 6 p.m This problem of definition does not of course affect the total length of sleep discussed in previous sections but will be of significance in the study of changes in the day sleep and the night sleep respectively

Earlier studies [1 2 4 7 19] have shown that the infant's sleep periods during the first few weeks of life are more evenly distributed over the twice-round the-clock period. A distinct day–night rhythm cannot be discerned The change over to a 24-hour pattern with longer night and shorter daytime periods of sleep occurs gradually According to Hellbrügge [8] a typical day–night pattern can be observed at the age of 4 weeks, but *not until the end of the first year of life* can it be considered to be fully developed Because of the irregularities during the first months of life it has proved difficult by the methods used in this study to obtain accurate values from the ages of 1 month and 3 months. For this reason the data reported below refer to the observations at 6 months and subsequent interviews up to 36 months.

Means and standard deviations for the number of hours of day sleep can be seen in Table 3 (page 108) These hours are *distributed among the number of sleep* periods set out in Table 6 (for the ages 6 12 24 and 36 months)

The need of a nap in the daytime seldom disappears suddenly from one day to another The break-off is usually preceded

mental factors. These are: the position of the child in the family dwelling space with special regard to overcrowding the gainful employment of the mothers, and children s separation during some period from the mothers. The χ^2 analyses has been per formed on data from the investigations at 1 2 and 3 years.

The found significant correlations with the tested factors concern first-born chil dren. At 1 year the first-born in this sample are in 99% analogous with only children. Thus, as regards bedtime resistance behaviour this category is the most troublesome ($\chi^2 = 9.07$ d.f 1 $p < .01$) The trend is the same for first-born and only children at the age of 3 years, but the correlation is significant at a lower level (.05 and .02, respectively)

As regards separation from the mother a correlation on the .05 level was obtained at the age of 3 This means that the child who had had experience of a wholly strange environment some time between 2 and 3 years of age (in hospital, in children home or with non-relatives) was more likely to offer resistance at bedtime than were the others. At other ages this relation was not found

No correlation was noted to overcrowd ing, nor to mother s gainful employment at any age levels.

(b) *Evening wakefulness*

Evening wakefulness denotes here that the child wakes up in the evening before the parents bedtime With this definition the length of the evening will of course vary according to the hour at which the particular family usually go to bed. As far as the child is concerned, evening wakeful ness could be included under night waking in the next section, but it will be dealt with separately for the following reasons. Because of the external factors the child would be more likely to wake up before the rest of the family have gone to bed, and if the child wakes in the evening this is generally less disturbing to the family than if it wakes in the night

The number of children waking regu larly in the evening decreases with increasing age (cf Fig. 5) Thus the trend is different from that shown earlier for resistance at bedtime

The statistical correlation between evening wakefulness and sex was tested for significance by the χ^2 technique. At the ages of 2 and 3 years there are no signif icant relations at 1 year the relation is significant at the 05 level, $\chi^2 = 4.47$ At this ge the boys wake in the evening less often than the girls.

Relation between evening wakefulness at

TABLE 9 *Relation between (a) resistance to bedtime preparation at different ages, (b) evening wakefulness at d fferent ages*

		χ^2	p	χ^2	p
9 months versus	12 months	4.81	< .05	12.82	< .001

12	36	2.81	< 10	4.47	< .05

is weak ($r = -17$ and $r = -16$ respectively significant on the 02 level) At 1 year there was no significant correlation.

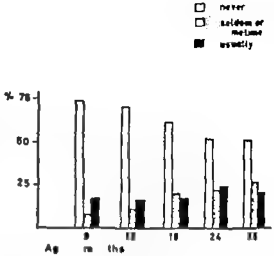

Fig 4 Percentage of children who are resistant at bedtime

III Bedtime Behaviour

Most parents expect the child to sleep from the time it has gone to bed until the family wake up in the morning The disturbances in and deviations from this ideal time-table can be divided into (a) resistance to bedtime preparations (b) evening wakefulness, and (c) night waking These forms of disturbances will here be discussed separately and with a view to their interrelationships.

(a) *Resistance to bedtime preparation*

We are concerned here with a disturbance that often occurs after the child has learnt to walk and shows resistance by refusing to go to bed offering opposition to being undressed, getting up once it has been put to bed, and lying awake grumbling and demanding the family's attention. This disturbance especially in children who cannot yet walk without aid also includes various behaviour in bed which greatly delays sleep Such a conduct lasting for some minutes is of course not recorded as a disturbance unless the mother experiences it as a troublesome situation. The information concerning this bedtime behaviour was collected from the age of 9 months. The grading of the replies will be found in interview form part II column 55 [8]

The percentage of children who go to sleep without disturbances decreases distinctly during the first three years of life The percentage of children who are usually (for grading cf. Fig 4) troublesome at bedtime rises slightly at 24 months and 36 months but the difference from the lower ages is not significant

A significant *sex-difference* as regards resistance at bedtime is obtained only at 3 years. The χ^2 value for the correlation is at 1 year 2 88 at 2 years 1 77 and at 3 years 7 87 The girls show predominance in the resistance group

Relation between resistance to bedtime preparation at different ages The relation between a child's bedtime behaviour at different ages, as expressed in χ^2 values, is shown in Table 9 The values are listed in order of the magnitude of the age-difference

The relationship that exists between bedtime behaviour at different age levels suggests a relative constancy of conduct which is particularly marked on comparison between the later ages, that is, when the child is older

Relation between resistance to bedtime preparation and some environmental factors The resistance behaviour at bedtime has been analysed in relation to some environ

hours but on the other hand, this would have yielded less accurate result with respect to the character of the disturbance. Therefore as regards time, the waking studied here is restrictedly nightly and would be more disturbing to the environment than would wakefulness at other times.

Fig 6 gives an idea of the incidence of night waking at the different age-levels. The data reported here refer only to the disturbances at the time of the interviews with a margin of about 1 week. Thus, the number of children who had sleep disturbances during the intervals between the visits will not influence the result.

The incidence of qualified night waking once or several times every night ranges from 14% to 24% in the age-period from 6 months to 3 years. If the frequency of 3 to 6 night wakings a week is added, the incidence of night waking will range between 23% and 39%. Percentage figures of a similar order has been reported in other studies (5 15). The term sleep disturbance does not necessarily imply that the waking is highly troublesome to the child or its environment although it occurs often in the course of the week. The inconvenience to the family is in most cases considerable however But at some ages there are marked divergencies between the factual incidence of waking and the frequency with which the mothers complain of the situation. This holds true in particular for the conditions at 1 month and at 3 years (cf page 106).

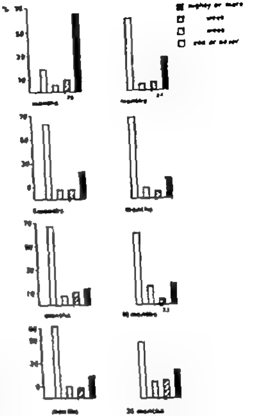

Fig. 6. Incidence of night waking at different ages. Percentage distribution.

In the analyses made to study the relation of night waking to various factors, the group with night disturbances includes unless otherwise stated, children who wake once or several times in the night and those who wake 3 to 6 times a week. Nightly disturbances once or twice a week are excluded.

The first analysis concerned *sex-differences*. The proportions of boys and girls in the night-waking group at 1., 24 and 36 months deviated only slightly from the expected distribution and the analysis gave very low χ^2 values.

Relation between night waking and total length of sleep. As to the children's total length of sleep at 12 months there was a correlation with the night waking, significant at the 5% level. This correlation implies that the children with night disturb-

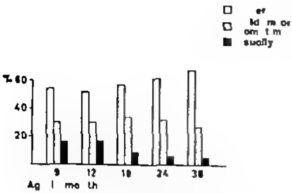

Fig 5. Percentage of children with evening wakefulness.

different ages These values are shown in Table 9 (page 113) listed in order of the magnitude of the age-difference similarly to those for resistant bedtime behaviour It will be seen from this table that for yearlong periods the evening wakefulness seems to be a constant feature in the sleeping pattern of some children.

Relation of evening wakefulness to some environmental factors In the analyses of evening wakefulness largely the same statistical calculations were made as in the case of resistant bedtime behaviour Two probably significant correlations were found. (*a*) Children who had been in hospital, children s homes or with non relatives some time between 2 and 3 years of age were disturbed in a higher degree than children without separation from their mothers ($\chi^2 = 4\ 04$ $p < 05$) No significant relationship was found to separation between 1 or 2 years of age (*b*) Children with separate bedrooms sleep with less disturbances in the evenings than children who had to share their bedrooms with the parents and/or siblings ($\chi^2 = 3\ 86$ $p < 05$ at 1 year and 4 62 $p < 05$ at 3 years of age At 2 years no significant correlation $\chi^2 = 2.51$)

Children of mothers with gainful employment outside the home were awake as often as other children ($\chi^2 = 0\ 03$)

Relation between resistance to bedtime preparation and evening wakefulness To find out whether the children who are troublesome at bedtime are also those who wake in the evening the significance of the correlation between the groups at 1 year and 2 years was tested by the χ^2 technique The correlation was not significant χ^2 values: at 1 year 2 44 at 2 years 0 03

(c) *Night waking*

Night waking is here defined as the interruptions of the child s sleep that occur between the parents bedtime and 6 a m unless caused by the family s early morning habits In order to distinguish between night waking and early (before 6 a m.) waking in the morning the latter was recorded separately In some cases especially in the first year of life it was difficult to decide where to draw the line between early morning wakefulness and night waking Almost without exceptions interruptions of sleep between 5 and 6 a.m were recorded as early morning wakefulness, and those before 4 a.m as night waking An interruption between 4 and 5 a.m was generally referred to the early morning group unless it was quite clear that the waking meant only a momentary break in a stretch of sleep hours. So on some occasions the situation was assessed from case to case the problem being to decide whether the child had broken off its longest stretch of sleep and then began a fresh sleep cycle of a more varying sleep–wakefulness pattern It would of course have been easier to draw the lines strictly at certain

hours but, on the other hand, this would have yielded a less accurate result with respect to the character of the disturbance. Therefore as regards time the waking studied here is restrictedly nightly and would be more disturbing to the environ ment than would wakefulness at other times.

Fig. 6 gives an idea of the incidence of night waking at the different age-levels. The data reported here refer only to the disturbances at the time of the interviews with a margin of about 1 week. Thus, the number of children who had sleep disturbances during the intervals between the visits will not influence the result.

The incidence of qualified night waking once or several times every night ranges from 14 % to 4 % in the age-period from 6 months to 3 years. If the frequency of 3 to 6 night wakings a week is added, the incidence of night waking will range between 23 % and 30 %. Percentage figures of a similar order has been reported in other studies (5 13). The term sleep disturbance does not necessarily imply that the waking is highly troublesome to the child or its environment, although it occurs often in the course of the week. The inconvenience to the family is in most cases considerable however. But at some ages there are marked divergencies between the factual incidence of waking and the frequency with which the mothers complain of the situation. This holds true, in particular for the conditions at 1 month and at 3 years (cf page 100).

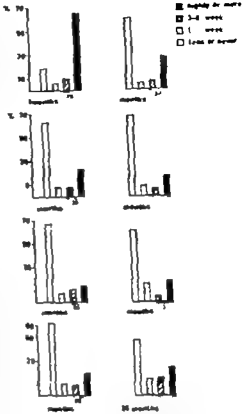

Fig. 6. Incidence of night waking at different ages. Percentage distribution.

In the analyses made to study the relation of night waking to various factors, the group with night disturbances includes, unless otherwise stated, children who wake once or several times in the night and those who wake 3 to 6 times a week. Nightly disturbances once or twice a week are excluded.

The first analysis concerned *sex-differences*. The proportions of boys and girls in the night-waking group at 1 24, and 36 months deviated only slightly from the expected distribution and the analysis gave very low χ^2 values.

Relation between night waking and total length of sleep. As to the children's total length of sleep at 1 months there was a correlation with the night waking, significant at the 5% level. This correlation implies that the children with night disturb-

The first analysis concerned *sex-d ffer ences* The proportions of boys and girls in the night-waking group at 12, 24, and 36 months deviated only slightly from the expected distribution and the analysis gave very low χ^2 values

Relation between night waking and total length of sleep As to the children s total length of sleep at 12 months there was a correlation with the night waking, signi ficant at the 5 % level. This correlation implies that the children with night disturb-

TABLE 10 *Relation between night waking at different ages*

		n	χ^2	p
3 months versus	9 months	157	12.39	< 001
6	12	160	17 48	< 001
6	24	161	3 6	< 03
6	36	156	4.6	< 05
12	24	167	13.59	< 001
12	36	160	14 97	< 001
24	36	155	6 34	< 02

ances sleep less than others The children were divided by length of sleep into 3 groups in which the frequency of night disturbances was studied (2×3-fold table) The first group comprised all those who slept shorter than the average group the second one was the average group and the third one those who slept longer (cf also Fig 3 page 108) $\chi^2 = 6.37$ d.f $= 2$ $p < 05$

The corresponding χ^2 values for 24 and 36 months were 3 33 d.f $= 2$ and 1 91 d.f $= 2$ *thus no significant correlations.* This difference may indicate that the night wakings at the later ages of 2 and 3 years are often shorter interruptions which do not reduce the number of sleep hours to any great extent

Relation between night waking at different ages of the same child The analyses were made after recording in a fourfold contingency table with those without sleep disturbances in one variable and the night-wakers in the other the correlation between the different ages was tested by the χ^2 technique (table 10)

In analogy with the results for bedtime behaviour and evening wakefulness it seems that for a long time night disturbances also form a recurring feature in the sleep-behaviour pattern of some children

Relation between night waking and evening wakefulness There is a positive correlation of night waking to evening wakefulness at 12 months ($\chi^2 = 6\ 05$ d.f. $=$ 1 $p < 05$) but the correlation is not significant at 24 months ($\chi^2 = 2.68$ d.f $= 1$) Accordingly the children who wake in the evening probably also wake in the night at the age of 1 year

Relation of night waking to some social and environmental factors Neither the family s social class, the child s position in the family overcrowding, separate bed room or the mother being gainfully employed nor the child s temporary separation from the mother show any significant relationships to night waking The analyses were made in fourfold contingency tables, where one variable included unbroken sleep and frequent night waking respectively at 1 *2 or 3 years of age* and the other comprised environmental factors at the same time

Relation of night waking to developmental quotient The correlation between night waking and the Brunet-Lézine quotient was analyzed at *6 9 12 18* and 24 months of age At 36 months Terman Merrill quotient was used Two fairly equal-sized groups with a distinct difference in mental development were compared in one group the quotients were at least ½ standard deviation below and in the other at least equally much above the average

None of the relations is significant although the value at 12 months comes close to showing a probably higher frequency of night waking in the children with a higher development quotient (χ^2 0 02, 1 63 3 79 1.33 0 51 0.24 respectively)

IV Night Disturbances During Long Periods

In the previous section dealing with the interruptions of night sleep the analyses concerned mainly the cross-sectional values and their relationships from relatively frequent interviews. As information about the sleep behaviour in the intervals between the interviews was also collected, a distinction can be made between children who slept permanently without disturbances and those who had spells of waking. The children were divided according to a 5-point scale the division being based on the frequency of night waking from 9 months to 3 years. The extremely good sleepers (group 1) were reported to wake very seldom during this period the estimated total spell of waking being at most weeks. In the group of extremely poor sleepers (group 5) the total spell of night waking in each child amounted at least to 1 year. Between these extremes, the rest of the children are grouped on a rising scale as regards the frequency of night waking. There is, thus, a marked difference in the night's rest between the children who fall into the extreme groups. These groups were then tested in various respects against other variables. The number of children in the different groups is as follows:

Group	*Children*
1 Extremely good sleepers	= 44
Good sleepers	= 40
3 Intermediate group	= 50
4 Poor sleepers	= 25
5 Extremely poor sleepers	= 40

(Insufficient dat on sleep were obtained in 1 case.)

T ble 11 shows the variables tested to est blish any correlations or differences between the extreme groups of children with long-continued sleep disturbances and long-continued unbroken nights.

The two groups of children compared differ greatly with respect to night sleep The children in one group have slept without disturbances almost every night for years, whereas those in the other group have wakened often and over a long period. In many other respects, however there are no dissimilarities Among the tested variables, the dwelling conditions and the time of weaning from the breast are, in fact, the only ones that give a probable significance Overcrowding reduces the possibilities for the child to be protected from light and sound in the surroundings In children who are particularly sensitive or who are light sleepers, these external stimuli associated with overcrowding may be a valid cause for waking or at least, tend to make the parents experience the child's night waking as disturbance and complication. Children at the ages with which we are concerned will usually in one way or other make their presence felt when they wake up.

The relationship to breast-feeding is more difficult to xplain. The weaning period occurs later throughout the group of poor sleepers (see Fig 7) The median age for last breast feed is 3 3 months for the good sleepers and 5 8 months for the poor sleepers. For comparison, it may be mentioned that in the total sample (n = 21?) half the children had had their last breast feed at the age of 4 months.

The relationship between late weaning and more frequent night waking is not revealed by cross-section analyses of the

total sample at the different age levels. χ^2 values are all below significance The reason why a relationship as demonstrated earlier for the more continuous night disturbances failed to appear in the total sample would be that at each age level there are in addition numerous temporary night disturbances that may conceal any associations with various factors in the extreme group of poor sleepers.

For the great majority of children who wake in the night temporarily or habitually at *for instance 12 or 24 months the* duration of breast-feeding is of no significance But in those with more permanent and troublesome sleep disturbances some sort of relationship seems to exist Whether it is causal or explained by coincidences of common factors in the child or the mother remains an open question Gottfarb *et al* [5] who also found a relationship between sleep disturbances and duration of breast feeding suggest that children whose mothers have insufficient milk but are still anxious to feed their babies themselves, would wake from hunger and that waking would thus become habitual

In the present study such a cause might be possible for about *half* of those who *have been defined as extremely poor* sleepers. They meet the criterion of having had sleep disturbances almost uninterruptedly since the period of breast feeding whether the weaning had been late (16 cases) or early (8 cases)

Night waking at 1 month is mostly interpreted as due to hunger and is treated by feeding If the child settles after the feed, hunger is taken to be the cause of the sleep disturbance The parents find either that the night feed comes later each night, until it coincides with the early morning feed, or that suddenly one night the child sleeps through without waking. When, at a later stage of infancy or in the first or second year the unbroken sleep is disturbed again, the causes of the disturbance are not so uniformly interpreted. But up to between 1 and 1½ years however night feeding is the method most usually tried, though without having the same effect as during the first few months of life (cf. page 120) To find out whether there is any relationship between the habit of night feeding at 3 months of age and later night waking at various ages, the statistical correlation was sought by means of χ^2 analyses in the total sample The results are set out in Table 12.

It will be seen that the relation was highly significant at 6 and 9 months, decreased with increasing age and finally disappeared This is readily explained by the fact that children who wake for a

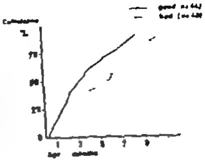

Fig. 7 Age of weaning in good and bad sleepers. —— = good (= 44); —— = bad (= 49).

night feed at 3 months will, to some extent, also do so at 6 9 and 12 months. In so far as night feeding is occasioned by hunger and this night waking is habit-forming the statistical correlation in an earlier phase should not cease to exist. Now the reverse is the case when the child is adjusted to an adequate feeding schedule the established correlations disappear and other causes of night disturbances supervene

In late-weaned children breast-feeding inadequacy might be one cause among others. We do not know if the habit-forming power is stronger when the child has passed 3 months of age. W cannot show it statistically nor exclude this possibility We know however that the infant sucking has emotional qualities as well Therefore we can also look upon night waking in children with breast-feeding of long duration as related to this emotional sphere in one way or another

night feed at 3 months will, to some extent also do so at 6, 9 and 12 months. In so far as night feeding is occasioned by hunger and this night waking is habit-forming the statistical correlation in an earlier phase should not cease to exist. Now the reverse is the case: when the child is adjusted to an adequate feeding schedule the established correlations disappear and other causes of night disturbances supervene.

In late-weaned children breast-feeding inadequacy might be one cause among others. We do not know if the habit-forming power is stronger when the child has passed 3 months of age. We cannot show it statistically nor exclude this possibility. We know however that the infant's sucking has emotional qualities as well. Therefore we can also look upon night waking in children with breast-feeding of long duration as related to this emotional sphere in one way or another.

The effect of the treatment methods used. In the case of children who have long periods of wakeful nights, the parents have the opportunity of trying various methods for settling. At each interview the mother stated what methods they tried and which of them had been most effective

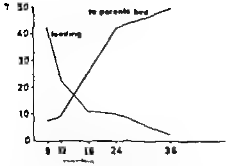

Fig 8. Most effective of methods used at various ages (bad sleepers).

In the extreme group of bad sleepers the results had evidently not been spectacular as the habit of waking in the night had persisted for a long time But on each particular night the waking could be offset with different degrees of success by various methods, and it is this preference for and confidence in a particular method that are expressed in the replies. The answers represent all sorts of methods which mirror the efforts of weary parents to handle the night wakefulness. The methods range from those of punishment (a few cases) to those aimed at making the child feel comfortable and secure The use of drugs is not common. The two methods which are used most commonly but which vary with the age of the child are feeding in the night and letting the child get into the parents' beds No other method alone is used more frequently than any one of these two The variations in the frequency of these methods at different ages will be seen in Fig 8

Summary

The study is part of a prospective longitudinal investigation which comprises 212 children chosen randomly from a Swedish urban community The sleep behaviour of the children which is reported here was followed up to the age of 3 years. Mean values with standard deviations for duration of sleep (total, day sleep and night sleep) at 6 9 12 18 24 and 36 months are presented The length of night sleep increases slightly but because the day sleep decreases much more the 3-year-old will on an average sleep nearly $2\frac{1}{2}$ hours less per 24 hours than will a 6-month-old baby The total length of sleep per 24 hours does not vary with the amount of day light hours. A calculation of correlation also shows that the possibilities to predict the length of sleep at a later stage of the child's life are small. The length of sleep showed no statistical correlation with a great number of tested environmental factors The latter included overcrowding and the mother being gainfully employed.

Analyses were made of various forms of sleep disturbances their frequency at 8 different age-levels and their continuity and associations with various environmental and constitutional factors For yearlong periods resistance to bedtime preparations, evening wakefulness and night waking form a recurrent feature in the sleep-behaviour pattern of some children. The incidence of night waking which at no age is below 23 is highest at 1 month being 75 %. The interruptions of night sleep show no relationship to the tested environmental variables, whereas the disturbances in the evening and in connection with bedtime preparation were found to be related to external stimuli and strange experiences to the child such as separation from the mother

Finally a comparison was made between children who had been bad sleepers

for just over 2 years and the extreme group of children who had slept without disturbances. Among the tested variables, only marked overcrowding and prolonged breast-feeding were related to a tendency to wakefulness.

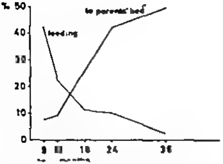

Fig. 8. Most effective of methods used at various ages (bad sleepers).

In the extreme group of bad sleepers the results had evidently not been spectacular as the habit of waking in the night had persisted for a long time. But on each particular night the waking could be offset with different degrees of success by various methods and it is this preference for and confidence in a particular method that are expressed in the replies. The answers represent all sorts of methods which mirror the efforts of weary parents to handle the night wakefulness. The methods range from those of punishment (a few cases) to those aimed at making the child feel comfortable and secure. The use of drugs is not common. The two methods which are used most commonly but which vary with the age of the child, are feeding in the night and letting the child get into the parents' beds. No other method alone is used more frequently than any one of these two. The variations in the frequency of these methods at different ages will be seen in Fig. 8.

Summary

The study is part of a prospective longitudinal investigation which comprises 212 children chosen randomly from a Swedish urban community. The sleep behaviour of the children which is reported here was followed up to the age of 3 years. Mean values with standard deviations for duration of sleep (total day sleep and night sleep) at 6, 9, 12, 18, 24 and 36 months are presented. The length of night sleep increases slightly but because the day sleep decreases much more the 3-year-old will on an average sleep nearly 2½ hours less per 24 hours than will a 6-month-old baby. The total length of sleep per 24 hours does not vary with the amount of day light hours. A calculation of correlation also shows that the possibilities to predict the length of sleep at a later stage of the child's life are small. The length of sleep showed no statistical correlation with a great number of tested environmental factors. The latter included overcrowding and the mother being gainfully employed.

Analyses were made of various forms of sleep disturbances, their frequency at 8 different age levels and their continuity and associations with various environmental and constitutional factors. For yearlong periods resistance to bedtime preparations, evening wakefulness and night waking form a recurrent feature in the sleep-behaviour pattern of some children. The incidence of night waking, which at no age is below 23 %, is highest at 1 month, being 75 %. The interruptions of night sleep show no relationship to the tested environmental variables whereas the disturbances in the evening and in connection with bedtime preparation were found to be related to external stimuli and strange experiences to the child such as separation from the mother.

Finally a comparison was made between children who had been bad sleepers

for just over 2 years and the extreme group of children who had slept without disturbances. Among the tested variables, only marked overcrowding and prolonged breast-feeding were related to a tendency to wakefulness.

THE PRADER-LABHART-WILLI SYNDROME REVIEW OF THE LITERATURE AND REPORT OF NINE CASES

by

Henry G Dunn

In 1956 Prader, Labhart and Willi (47) in Switzerland first described a syndrome of obesity, small stature, oligophrenia and acromicria (i.e. small hands and feet), regularly preceded by severe amyotonia in infancy. Variable minor degenerative stigmata were also noted in children of both sexes, and the boys had a hypoplastic flat scrotum with inguinal or abdominal retention of testes. The patients had all been extremely limp as newborns, unable to cry or suck, with absent or weak tendon reflexes. They passed their locomotor milestones with delay. About the second year they began to be obese, and delayed growth and mental retardation became noticeable, while the hypotonia and weakness improved and the deep tendon reflexes became stronger. In the males the development of puberty appeared to be delayed and incomplete. The oldest boy developed diabetes mellitus at 17 years; his excretion of gonadotrophin was raised.

Once again in 1956 these Swiss authors, together with Fanconi (48), described the syndrome at the 8th International Congress of Paediatrics. In 1961 Prader and Willi (49) presented an analysis of 14 cases at the 2nd International Congress on Mental Retardation, and the published summary was a little more detailed than the previous abstracts. They added that the mother usually noted diminished fetal movements during the pregnancy and that the average birth weight was less than 3 kg. The later intelligence quotient (I.Q.) was said to be about 40 to 50. Two out of five patients above the age of 1[illegible] years had developed diabetes mellitus, and a third had pre-diabetes at 15 years. In both the established cases the diabetes was stable, without emaciation or acidosis, and thus suggestive of the maturity-onset type of disease. One of the two patients had died of diabetic angiopathy at 28 years. The authors were unable to indicate a definite cause for this syndrome but suggested a genetic defect, probably with a recessive mode of inheritance. There were, however, no known cases of the occurrence of the syndrome in siblings or in more distant relatives.

Again, in 1961, Laurance (38) described six similar cases in boys at the annual meeting of the British Paediatric Association. The patients were chromatin-negative and had normal chromosomes. In the same year the present writer, together with Drs. Ford, Auersperg and Miller (12), published a report concerning a boy who had benign congenital hypotonia with hypogenitalism and had been found to have an extra small chromosome in the G group. The clinical findings in this boy corresponded closely to those of the syndrome described by Prader and his colleagues. The extra small chromosome was later identified as a Y, so that the patient has an XYY karyotype.

In 1962 Gabilan (19) reported four cases in France, and further details of these patients were given by Royer (55) in the following year. The first two of these children were siblings, and the parents of the fourth patient were stated to be consanguineous, hence these cases support the assumption of a recessive genetic defect. However the siblings must be described as atypical in their clinical features, since both had seizures in early infancy, both became obese unusually early (at 8 and 6 months, respectively), both showed excessive sensitivity to intravenous insulin, with hypoglycemia unresponsiveness, and the boy had palpable testes. The fourth patient, a girl who developed diabetes mellitus, had not shown any amyotonia in the neonatal period and thus lacked an important feature of the syndrome. Also in 196[illegible], Zellweger and his colleagues (72) in the United States described a boy with characteristic symptomatology who, in addition, had an abnormal urinary tract. The authors stated that they had observed 10 cases of the syndrome described by Prader and Willi, and that testicular biopsies in a 5-year-old and a 3-year-old patient had shown infantile testes without germinal cells. A chromo-

somal aberration had been found in only one case, a boy mentioned in a previous paper (71), who had a 14–18 translocation.

In 1963 we summarized our experience with 4 Canadian cases of the condition (13) Clinically in addition to the features described by Prader and his colleagues, these patients presented dental abnormalities, *particularly* enamel defects, and abnormalities of ocular movements.

In 1964 Forssman and Hagberg (18) described a Swedish boy of 10 years with the syndrome who had an I Q of no more than 20 The presence of pre-diabetes was demonstrated by the use of the cortisone-glucose tolerance test (17) The chromosomes in this boy were normal, but the writers drew attention to a report by Bühler *et al* (4) who had described a boy with similar clinical findings and with a karyotype suggestive of a translocation of two autosomes in the 13–15 group In the same year Sánchez Villares *et al* (56) reported a case in Spain. Evans (16) published details of 8 British cases, all boys. In these, gross obesity had developed at a mean age of $2^1/_2$ years. The I.Q varied from 41 to 87 with a mean of 61 Glucose tolerance tests showed impairment in 4 of the 8 patients, and 2 with normal results had deficient glucose tolerance after cortisone. Evans suggested that the patients should be investigated for the presence of an insulin antagonist.

In 1965 two notable cases were reported in France. One, a boy of $13^1/_2$ years, appeared to have mosaicism for trisomy of a D chromosome (group 13–15) (54) The other a boy of 3 years 8 months, had already developed diabetes at the age of 6 months (36) Monnens and Kenis (44) encountered 3 cases in Holland and drew attention to disturbed diurnal variation of the plasma 11 hydroxy-corticosteroid level in 2 of them.

In 1966 Hooft *et al* (29) gave a detailed description of 4 patients in Belgium. Independently of our own observations (13) these authors found a convergent strabismus in all 4 and marked tooth decay in 2 of the children. Sugarman and Boder (61) described the occurrence of the syndrome in an American negro boy

In 1967 Laurance (39) summarized his findings in 9 patients, including two girls. He emphasized the characteristic facies, with prominent forehead and slightly open, fish-like mouth. In one of two muscle biopsies in these cases Dr A. L. Woolf noted that intravital staining with methylene blue showed some finely beaded fibers in the smaller nerve bundles, similar to those seen in Werdnig-Hoffmann's disease, but less numerous. In a third muscle biopsy Dr V Dubowitz found a normal content of glycogen and of several tissue enzymes. The palm and finger prints of 6 boys were examined by Professor P E. Polani who found an *atd* angle exceeding 57 in 2 and a hypothenar loop pattern in 5 whereas these features are present in at most 10 and 15% of the normal population, respectively In another article, Hoefnagel *et al.* (28) reported 4 further American patients. Dubowitz (10) presented ? new British cases one of these had an abnormal chromosome No. 16, which was also present in the mother Juul and Dupont (31) described the oldest known patient with this syndrome, a man aged 43 years, whose endocrine system was investigated in detail

It will thus be seen that about 70 cases of the syndrome had been recorded by the end of 1967 mostly in Europe. The purpose of the present paper is to summarize our own findings in a total of 9 patients and to review the features of the condition.

CASE REPORTS

Case 1

B.M. is the boy already published in 1961. He remains the youngest of 3 children, the mother also had 2 miscarriages. In the family history it is noted that the maternal grandmother has diabetes mellitus and that a maternal uncle failed to take feedings satisfactorily after birth and died at 3 months. The present pregnancy was described as normal except for slight "spotting" at 6 weeks. Labor occurred 10 days after term and ended in a fairly easy breech delivery after less than 3 hours. The baby weighed 2892 g and was limp and blue at birth but responded to resuscitation.

At 6 days, when I first saw him, he was fair-haired and still listless and limp with a whining cry lying curled up with hunched-up shoulders and adducted hips. The palpebral fissures had slight mongoloid slant. The lower jaw was slightly short. The pinnae appeared soft, and the external auditory meatuses were unusually narrow as in Down syndrome. The scrotum was small and empty The infant was generally hypotonic. There was a feeble Moro response, and no stepping reflex was obtained. He sucked poorly No tendon reflexes could be elicited. A weak withdrawal response was demonstrated in the legs.

Subsequently the infant remained so weak and sucked so poorly that his mother gave him formula by spoon from the *ge of 7 /* weeks. However he did smile at

It will thus be seen that about 70 cases of the syndrome had been recorded by the end of 1967 mostly in Europe. The purpose of the present paper is to summarize our own findings in a total of 9 patients and to review the features of the condition.

CASE REPORTS

Case 1

B. M. is the boy already published in 1961 He remains the youngest of 3 children the mother also had 2 miscarriages. In the family history it is noted that the maternal grandmother has diabetes mellitus and that a maternal uncle failed to take feedings satisfactorily after birth and died at 3 months. The present pregnancy was described as normal except for slight spotting at 6 weeks. Labor occurred 10 days after term and ended in a fairly easy breech delivery after less than 3 hours. The baby weighed 2892 g and was limp and blue at birth but responded to resuscitation.

At 6 days, when I first saw him, he was fair-haired and still listless and limp with a whining cry lying curled up with hunched-up shoulders and adducted hips. The palpebral fissures had a slight mongoloid slant. The lower jaw was slightly short. The pinnae appeared soft, and the external auditory meatuses were unusually narrow as in Down syndrome The scrotum was small and empty The infant was generally hypotonic. There was a feeble Moro response, and no stepping reflex was obtained. He sucked poorly No tendon reflexes could be elicited. A weak withdrawal response was demonstrated in the legs.

Subsequently the infant remained so weak and sucked so poorly that his mother gave him formula by spoon from the age of 7 / weeks. H ever he did smile at

Fig. 4. Case 1. Small penis and scrotum at 2 years 4 months, testes undescended.

thout support at 18 months and to sit up by himself at 2 years 1 month (Fig. 1). He finally walked freely at 3 years 3 months.

His weight at 9 months was only 7250 g and thus just below the third percentile. At 18 months there was little change in the weight, while the length of 74 cm had also become significantly small for his age; only eight teeth had erupted. At 2 years 1 month, the upper canines and second molars had not yet come through. The upper medial incisors showed enamel hypoplasia at their cutting edges (Fig. 2). Since the serum protein-bound iodine level was only 3.4 μg/100 ml and the bone age was greatly retarded, he was then given thyroid therapy at 26 months, and some acceleration of growth may have resulted (Fig. 3). He became significantly obese at 4 years, while the stature remained below the tenth percentile. All the deciduous teeth soon became carious and had to be extracted. The penis remained small, scrotum flat, and the testes undescended (Fig. 4).

Psychometric testing at 31 months indicated a mental age of 25 months on the Merrill-Palmer scale, i.e. at the tenth percentile for his age. On the Vineland Social Maturity Scale his motor achievements at that time attained the equivalent for 20 months, while non-motor items corresponded to those of a mental age of about years. However, his subsequent mental development was slow and at 6 years he obtained an I.Q. of only 51 on the Cattell Infant Intelligence Scale and about 50 on the Peabody Picture Vocabulary Test.

The results of investigations are listed in the previous article and in Tables 3 to 5 and 9, so only the abnormal findings will be mentioned here. X-ray examination showed marked hypoplasia of muscle masses in the arms as well as marked delay in the bone age, and slender and poorly mineralized bones. A muscle biopsy of the right deltoid and quadriceps showed somewhat small muscle fibers, but was otherwise normal. The chromosomal karyotype in tissue culture of fibroblasts from prepuce and muscle demonstrated an extra small chromosome, and later leukocyte culture showed that this extra chromosome was Y (Fig. 5).

At 8 years this boy now attends a special class for retarded children. He remains grossly overweight (49 kg, i.e. twice normal or +8 SD for height-age) despite attempts at reducing diet, physical activation and anorexigenic drugs. He has distension striae over the buttocks. The penis and scrotum remain small and the testes undescended. He still talks mostly in single words or short sentences, with poor articulation. He has over

Table 2. *Physical findings in 9 patients with Prader Labhart Willi syndrome*

Stature below mean for age 6/9
Stature more than 1 SD below mean for age 5/9
Stature more than 2 SD below mean for age 3/9
Obesity after infancy—extremely in 8/9
Head circumference normal (±2 SD for age) or increased 9/9
Anterior fontanelle open after age of 18 months 4/4
Small feet and hands (acromicria) 9/9
Undescended testes and small scrotum in boys 7/7
Amyotonia (benign congenital hypotonia) in infancy 9/9
Early caries 6/7 with enamel hypoplasia in 4/6
Phimosis in boys 4/5
Strabismus 7/9
Pes planus 7/9
Attractive facial features with delicate mouth and fair or auburn hair 4/8
Poor modelling of pinnae 4/9
Short toe nails 4/9
Arched palate 3/9
Bilateral simian creases 2/9 (unilateral in one other)
Clinodactyly 2/9
Mongoloid slant of palpebral fissures 2/9
Brushfield spots on irides 2/9
Narrow external auditory meatus 2/9
Partial syndactyly 1/9
Increased palm creasing 1/9
Bifid uvula 1/9

action of the inferior oblique muscle of the right eye. He is only mildly hypotonic, but the tendon reflexes are all sluggish (+1). The gait remains cautious and waddling. The behavioral development is indicative of an overall mental age of little more than 4 years according to the Gesell schedule. The bone age is still significantly retarded (4 to 5 years). The cortisone-glucose tolerance test gives no indication of pre-diabetes.

Case 2

G Mc., another boy, is the youngest of 6 children, and the mother also had 3 miscarriages after the birth of the fifth child, who was 14 years old when our patient was born. The boy's siblings are all healthy. A paternal uncle died at 3 to 4 months after incision of an abscess. The mother had some vaginal bleeding at 6 weeks and 6 months and was found to have glycosuria during this pregnancy. She noted little fetal movement. She went into labor spontaneously one week before term and was delivered by Cesarean section because of fetal distress. The infant weighed 2240 g and seemed depressed but was resuscitated. He remained limp and was kept in an incubator receiving formula with the help of a feeder for two weeks. He continued to take feedings slowly and his weight remained over 1 SD below the mean throughout the first year (Fig. 6). He followed with his eyes at 2 months and smiled in response at 2½ months. At 3 months he was re-admitted to hospital with bronchitis and weak cough.

When I first saw him, he was nearly 4 months old and had only just begun to raise his head in the prone position. The palate was moderately arched. The scrotum was small, and the testes were undescended. He had a hampering cry and lay limply on his back but followed

of about 3 / years, i.e. D.Q. of about 70. He still talked mostly in single words or short sentences. Overaction of both inferior oblique muscles persisted. There was still some general hypotonia, with sluggish tendon reflexes (+1), and the plantar and *Chaddock* responses were equivocal. The gait was wide-based and somewhat waddling. Unfortunately the parents objected to blood sugar investigations.

Case 3

W.W. another boy is the youngest of 3 children. Both parents belong to large sibships, and the family history is non-contributory except that there was gap of 14 years between the birth of the second child and that of our patient. The pregnancy was normal, though the mother commented that the *fetal* movements were weak. Labor occurred about 2 weeks after term and lasted about 4 hours; the *fetal* heart rate was somewhat slow at the second stage, but delivery was soon effected. The placenta was small and appeared infarcted. The birth weight was 3218 g. The infant cried only feebly and appeared cyanosed. On resuscitation his condition improved, but he remained limp during the first month, with little crying or spontaneous movement. He had to be fed by gavage for 3 weeks and then with feeder.

When I first saw him he was 4 / months old and was still unable to raise his head prone. The irides showed Brushfield spots, and both palms had bilateral transverse creases. Otherwise he resembled the boys described previously.

Fig. 8. Case 2. The child has pleasant features like Case 1. Note overaction of inferior oblique muscle of right eye.

Fig. 9. Case 3. Facies at 13 months. Note convergent strabismus and Brushfield spots on irides.

At 7 months he had learned to seize and transfer objects, remained weak and had developed convergent squint (Fig. 9). The bone age was significantly retarded. The conduction velocity in motor fibers of the median nerves was normal, and an electrocardiogram (ECG) and electroencephalogram (EEG) were within normal limits. A muscle biopsy from the right quadriceps showed normal histology. The spinal fluid was normal. Other investigations are listed in Tables 3 to 5 and 7.

This boy gained eight better during the first year than the two previous patients (Fig. 10). At 13 months he was pleasant and auburn-haired, still hypotonic, lying in the frog position (Fig. 11). The scrotum and penis were small and the testes undescended. The feet exhibited short toenails and mild pes planus.

At 2 years he became significantly obese. The convergent squint was corrected surgically; the resected right lateral rectus muscle was normal on section except that it contained some fibrous tissue. Leukocyte culture revealed normal chromosomal karyotype except that both the boy and his father have a long Y chromosome (of about the same length as the group 16–18), and in 19 of 82 cells the long arm of one of the $6-12+X$ chromosomes had a prominent secondary constriction.

At 4 years 7 months this patient was markedly obese (over 8 SD above the mean for his height-age). There much dental caries. The phalanges were poorly modelled (Fig. 12). Distension striae were noted in both groins, and he had "buffalo hump" and prominent buttocks.

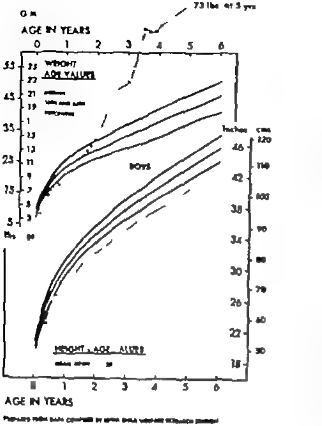

Fig 6. Case – Growth chart. Note marked increase in weight after first year with persistently small stature

with his eyes, sucked quite well and became slightly active at the sight of a dangling toy. Hypotonia and weakness affected trunk and limbs, and the musculature was poorly developed. The tendon reflexes were present but depressed (+1), and the ankle jerks were represented by a mere flicker. Sensation to pinprick appeared intact; the abdominal skin reflexes were present. Skin scratch caused a normal flare response. An *electromyogram* and motor conduction velocity in the left median nerve (36.5 m sec) were normal.

At 7 / months he had learned to seize and transfer objects, but no teeth had erupted as yet and he had an intermittent esotropia as well as *overaction of the inferior* obliques. The head was still unstable in the erect posture. Weakness in the limbs was most marked proximally. X-ray examination of the left arm showed an unusually small muscle mass, while the bony development of hand and wrist was that of a newborn and thus significantly *retarded. Other investigations are listed in Table 3.*

At 21 months this infant was not yet walking freely and had only 4 [illegible] 5 words, but his appetite had improved and the weight had risen above the mean, while the length was nearly 2 SD below the mean for his age (Fig. 6). The anterior fontanelle was still open to a fingertip, head circumference normal. Only the incisor teeth had erupted as yet, and a right upper incisor showed poor enamel on its anterior surface, with early caries. He was beginning to be well-nourished, with small hands and feet (Fig. 7). The joints were generally lax. The squint, *with overacting inferior obliques, was noted again (Fig. 8).* The penis and scrotum remained small, and the prepuce was phimotic. The prostate gland was palpable rectally. Circumcision was *performed,* and fibroblast tissue culture from the prepuce showed a normal male karyotype. Bone development was still that of a newborn.

At about / years this boy became significantly obese. At 5 years his height remained only just above the lower limit of the normal range, whereas the weight of 33.. kg was nearly twice the normal, and no less than 8 SD above the mean for his height-age (Fig. 6). His teeth had not become grossly carious, possibly because fluoride had been administered. He was reported to be somewhat stubborn but usually cheerful and good-natured. On the Gesell schedule he had a mental age

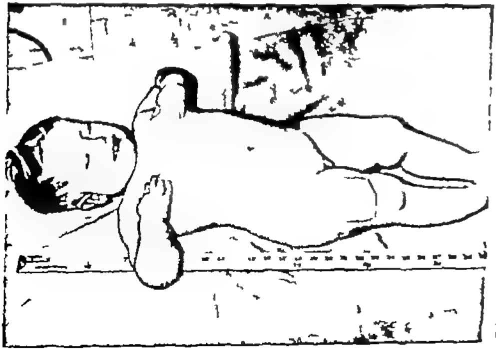

Fig 7. Case – Patient's appearance at .1 months, showing early obesity

of about 3 / years, i.e. D.Q. of about 70. He still talked mostly in single words or short sentences. Overaction of both inferior oblique muscles persisted. There was still some general hypotonia, with sluggish tendon reflexes (+1), and the plantar and Chaddock responses were equivocal. The gait was wide-based and somewhat waddling. Unfortunately the parents objected to blood sugar investigations.

Case 3

W. W. another boy, is the youngest of 3 children. Both parents belong to large sibships, and the family history is non-contributory except that there was gap of 14 years between the birth of the second child and that of our patient. The pregnancy was normal, though the mother commented that the fetal movements were weak. Labor occurred about 2 weeks after term and lasted about ¾ hours, the fetal heart rate was somewhat slow in the second stage, but delivery was soon effected. The placenta was small and appeared infarcted. The birth weight was 3218 g. The infant cried only feebly and appeared cyanosed. On resuscitation his condition improved, but he remained limp during the first month, with little crying or spontaneous movement. He had to be fed by gavage for 3 weeks and then with feeder

When I first saw him he was 4 / months old and was still unable to raise his head prone. The irides showed Brushfield spots, and both palms had bilateral transverse creases. Otherwise he resembled the boys described previously

Fig 9 Case 3 Facies at 13 months. Note convergent strabismus and Brushfield spots on irides.

Fig 8 Case The child has pleasant features like Case I Note overaction of inferior oblique muscle of right eye.

At 7 months he had learned to seize and transfer objects, remained weak and had developed convergent squint (Fig. 9). The bone ge was significantly retarded. The conduction velocity in motor fibers of the median nerve was normal, and an electrocardiogram (ECG) and electroencephalogram (EEG) were within normal limits. A muscle biopsy from the right quadriceps showed normal histology. The spinal fluid was normal. Other investigations are listed in Tables 3 to 5 and 7

This boy gained weight better during the first year than the two previous patients (Fig. 10). At 13 months he was pleasant and auburn-haired, still hypotonic, lying in the frog position (Fig. 11). The scrotum and penis were small and the testes undescended. The feet exhibited short toenails and solid pes planus.

At 2 / years he became significantly obese. The convergent squint was corrected surgically: the resected right lateral rectus muscle as normal on section except that contained some fibrous tissue. Leukocyte culture revealed normal chromosomal karyotype except that both the boy and his father ha a long Y chromosome (of about the same length as the group 16–18), and in 19 of 82 cells the long arm of one of the 6 – 12 + X chromosomes had prominent secondary constriction.

At 4 years 7 months this patient was markedly obese (over 8 SD above the mean for his height-age). There much dental caries. The pinnae were poorly modelled (Fig. 12). Distension striae were noted in both groins, and he had "buffalo hump" and prominent buttocks.

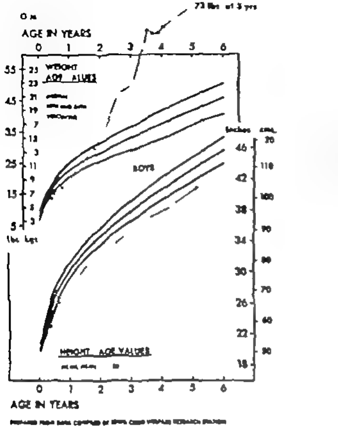

Fig 6. Case 2. Growth chart. Note marked increase in weight after first year with persistently small stature.

with his eyes, sucked quite well and became slightly active at the sight of a dangling toy. Hypotonia and weakness affected trunk and limbs, and the musculature was poorly developed. The tendon reflexes were present but depressed (+1) and the ankle jerks were represented by a mere flicker. Sensation to pinprick appeared intact; the abdominal skin reflexes were present. Skin scratch caused a normal flare response. An electromyogram and motor conduction velocity in the left median nerve (36.5 m/sec) were normal.

At 7 / months he had learned to seize and transfer objects, but no teeth had erupted as yet and he had an intermittent esotropia as well as overaction of the inferior obliques. The head was still unstable in the erect posture. Weakness in the limbs was most marked proximally. X-ray examination of the left arm showed an unusually small muscle mass, while the bony development of hand and wrist was that of a newborn and thus significantly retarded. Other investigations are listed in Table 3.

At 21 months this infant was not yet walking freely and had only 4 to 5 words, but his appetite had improved and the weight had risen above the mean, while the length was nearly 2 SD below the mean for his age (Fig. 6). The anterior fontanelle was still open to a fingertip, head circumference normal. Only the incisor teeth had erupted as yet, and a right upper incisor showed poor enamel on its anterior surface, with early caries. He was beginning t be well-nourished, with small hands and feet (Fig. 7). The joints were generally lax. The squint, with overacting inferior obliques, was noted again (Fig. 8). The penis and scrotum remained small, and the prepuce was phimotic. The prostate gland was palpable rectally. Circumcision was performed, and fibroblast tissue culture from the prepuce showed a normal male karyotype. Bone development was still that of a newborn.

At about ∠ / years this boy became significantly obese. At 5 years his height remained only just above the lower limit of the normal range, whereas the weight of 33.2 kg was nearly twice the normal, and no less than 8 SD above the mean for his height-age (Fig. 6). His teeth had not become grossly carious, possibly because fluoride had been administered. He was reported to be somewhat stubborn but usually cheerful and good-natured. On the Gesell schedule he had a mental age

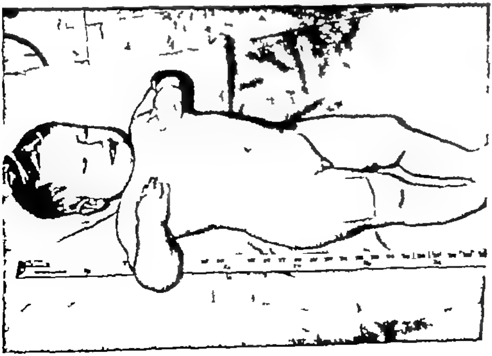

Fig 7. Case 2. Patient's appearance at 1 months, showing early obesity

obese at about 20 years. Otherwise the family history is non-contributory but the father was raised by grandparents and knows little of the family on his side. During the pregnancy with our patient the fetal movements seemed inadequate. Labor lasted about 8 hours, with breech presentation, and during the last half hour the infant passed meconium. Although delivery occurred at least one month after the expected time, she weighed only 2920 g. At birth she had a weak cry and was limp but was placed in an open crib. She remained markedly hypotonic and had to be gavaged for five weeks. "She did not even whimper for three months." Then she gradually became stronger but she only managed to roll around the floor at 1 year and was still unable to remain sitting at that time. Shortly thereafter she learned to say the first words.

At about 1 ½ years she pulled herself to the sitting position. She was then placed on thyroid therapy partly because her serum protein-bound iodine level was only 3.8 µg/100 ml. The weight then rose, and at 2 years 4 months she had become significantly overweight (Fig. 13). Her bone age was normal even before she was given thyroid. The child walked freely at 2 ½ years. She was described as pleasant and cheerful but stubborn.

When I saw her she was nearly 5 years old and was markedly obese, fair-haired and resembled the first 3 patients in her facial features (Fig. 14). She had a lordotic posture (Fig. 15). Her height was just above the lower limit of the normal range, whereas the weight was significantly (+3 SD) in excess of normal even for her actual age. The medial incisors showed enamel defects

Fig. 14. Case 4. Pleasant features and fair hair resemble those of Cases 1 and 2.

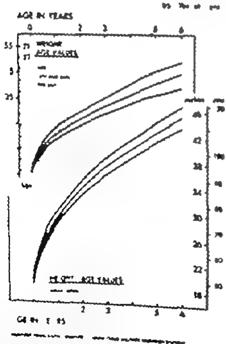

Fig. 13. Case 4. Growth chart, showing rising weight with persistently small stature.

along the incisal edges, and there was also considerable caries. The phalanx was poorly differentiated. Both hands exhibited delicate fingers and transverse palm creases. The feet were somewhat flat, with spoon-shaped toenails. The joints were generally lax. Her speech was satisfactory. The eye movements were normal. There was general moderate hypotonia, with fair power. The tendon reflexes were only doubtfully present in the arms, but the knee and ankle jerks were satisfactory. Coordination was fair but somewhat awkward and shuffling. Her overall behavioral development appeared to be barely at the level of 3 years according to the Gesell schedule so that her D.Q. was about 60. Her chromosomes were normal female.

At nearly 7 years this girl attended a school for retarded children. She weighed 34.8 kg despite attempted dieting. On the Wechsler Intelligence Scale for Children (W.I.S.C.) she had a verbal I.Q. of 71, performance I.Q. 47, full-scale I.Q. 56. On the Goodenough Draw-a-Man Test she obtained an I.Q. score of 70 and on the Vineland Social Maturity Scale S.Q. 80. Two glucose tolerance tests gave divergent results but a cortisone-glucose tolerance test proved normal. Other investigations are listed in Tables 3 to 5.

Case 5

J. W. is the fifth son of healthy parents. He has no sisters, and his brothers are normal, though the second eldest is reported to have been an inactive plump baby

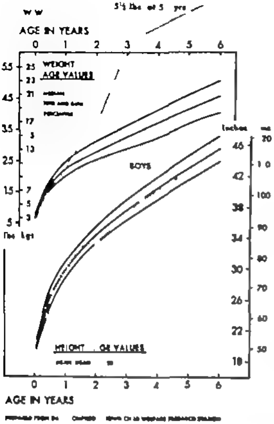

Fig 10 Case 3 Growth chart.

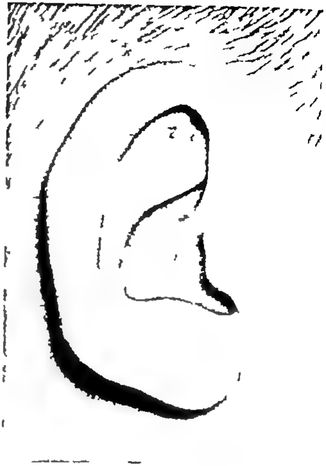

Fig 1 Case 3 Right ear showing poor modelling of pinna.

The appearance of the genitals was unchanged. He had a tendency to echolalia. He was still somewhat hypotonic, with sluggish tendon reflexes (+1) A month later the I.Q. was 69 on the Stanford-Binet Scale, while he scored an I.Q. of 75 on the Goodenough Draw-a-Man test and S.Q. 79 on the Vineland Social Maturity Scale. A glucose tolerance test proved normal but a prednisone-glucose tolerance test gave a significantly different result, with a 2 hour blood sugar value of 179 mg/100 ml and thus indicated a pre-diabetic state (Fig. 27).

Case 4

D M. was the first girl among our patients. She is the second of three children. The parents and siblings are healthy The mother has a maternal half-aunt who is mentally "slow" reached Grade 8 in school and became

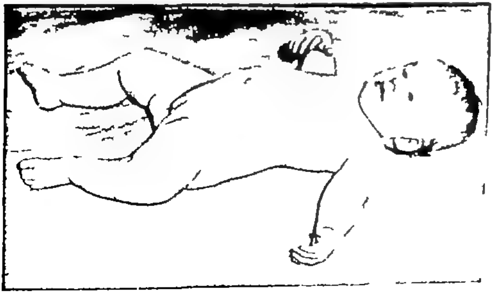

Fig 11 Case 3 Patient lying in frog position at 13 months.

obese at about 20 years. Otherwise the family history is non-contributory but the father was raised by grandparents and knows little of the family on his side. During the pregnancy with our patient the fetal movements seemed inadequate. Labor lasted about 8 hours, with breech presentation, and during the last half hour the infant passed meconium. Although delivery occurred at least one month after the expected time, she weighed only 2720 g. At birth she had a weak cry and was limp but was placed in an open crib. She remained markedly hypotonic and had to be gavaged for five weeks. "She did not even whimper for three months. Then she gradually became stronger but she only managed to roll around the floor at 1 year and was still unable to remain sitting at that time. Shortly thereafter she learned to say the first words.

At about 1 ½ years she pulled herself to the sitting position. She was then placed on thyroid therapy partly because her serum protein-bound iodine level was only 3.8 µg/100 ml. The weight then rose, and at 2 years 4 months she had become significantly overweight (Fig. 13). Her bone age was normal even before she was given thyroid. The child walked freely at 2 ½ years. She was described as pleasant and cheerful but stubborn.

When I saw her she was nearly 5 years old and was markedly obese, fair-haired and resembled the first 3 patients in her facial features (Fig. 14). She had a lordotic posture (Fig. 15). Her height was just above the lower limit of the normal range, whereas the weight was significantly (+3 SD) in excess of normal even for her actual age. The medial incisors showed enamel defects

along the incisal edges, and there was also considerable caries. The phalanges were poorly differentiated. Both hands exhibited delicate fingers and transverse palm creases. The feet were somewhat flat, with spoon-shaped toenails. The joints were generally lax. Her speech was satisfactory. The eye movements were normal. There was general moderate hypotonia, with fair power. The tendon reflexes were only doubtfully present in the arms, but the knee and ankle jerks were satisfactory. Coordination was fair but somewhat awkward and shuffling. Her overall behavioral development appeared to be barely at the level of 3 years according to the Gesell schedule so that her D.Q. was about 60. Her chromosomes were normal female.

At nearly 7 years this girl attended a school for retarded children. She weighed 18.8 kg despite attempted dieting. On the Wechsler Intelligence Scale for Children (W.I.S.C.) she had a verbal I.Q. of 71, performance I.Q. 47, full-scale I.Q. 56. On the Goodenough Draw-a-Man Test she obtained an I.Q. score of 70 and on the Vineland Social Maturity Scale S.Q. 80. Two glucose tolerance tests gave divergent results but cortisone-glucose tolerance test proved normal. Other investigations are listed in Tables 3 to 5.

Case 5

J.W. is the fifth son of healthy parents. He has no sisters, and his brothers are normal, though the second eldest is reported to have been an inactive plump baby

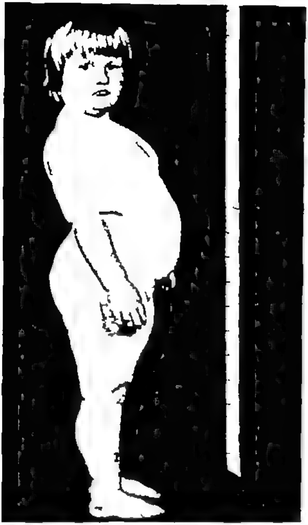

Fig 15 Case 4 The child has a lordotic posture· her obesity is most marked on the trunk and proximal part of limbs.

whose testes only descended after hormone injections at 9 to 10 years. The mother had no miscarriages, but there was a gap of 7 years between the birth of the 4th boy and that of our patient. During this pregnancy the mother had slight vaginal bleeding at 3 months and later thought the fetal movements were *excessive* at times. Labo was *induced medically at term* and proceeded normally lasting about 6 / hours. At birth the infant weighed 3884 g. He obtained an Apgar score of 9 but was immediately noted to be lethargic and floppy From the fifth day he was fed by gavage. Lumbar puncture showed normal spinal fluid. A subcutaneous injection of neostigmine 0.25 mg did not improve his tone. Despite his limpness he turned his eyes to light and sound at three weeks.

When I first saw him he was six weeks old. H lay *limply on his side (Fig 16)* and had a somewhat elon gated head, with slightly short lower jaw and wide fontanelle. The joints were generally lax. The scrotum was small, with a central dimple, and did not contain any testes. The penis was normal in size, with phimotic prepuce. The infant was able to suck and had Moro and asym-metrical tonic neck reflexes as well as plantar grasping, but he was generally hypotonic and unable to raise his head prone, to flex his hips when erect or to make any stepping movements. No rooting response was obtained, and there was pronounced head lag on arm traction. He had intermittent alternating esotropia, and the facial movements were restricted. The weakness of the limbs appeared greatest proximally No tendon reflexes were obtained except flickers of knee jerks. A buccal smear was chromatin-negative Leukocyte culture showed a normal male complement of chromosomes. Electromyo-graphy and measurement of motor conduction velocity in the right median nerve gave normal results. Muscle biopsy from deltoid showed no abnormality and intra-vital staining with methylene blue demonstrated normal motor end plates. Other investigations are listed in Tables 3 and 5 to 7

At 2 / months the infant became able to take formula from a feeder *At 3 months he was beginning to smile.* At 4 months he took bottle feedings. At 4 / months he raised his head prone At 11 / months he began to *crawl and to wave "bye-bye*

At 1 year he weighed 9186 g and had developed such a good appetite that his mother became concerned. He was then a pleasant boy with dark-blood hair and a some-what narrow head (Fig. 17). His length and head circum-ference were normal. Only six incisor teeth had erupted. He had a moderate inspiratory stridor He picked up objects with pincer grasp and rolled over skillfully but was still unable to retain sitting unsupported. There was no Landau postural response, but he did have protective extension of the arms when lowered head-first. The hypotonia was less marked and he no longer slipped through the fingers when held aloft by the axillae but *no tendon reflexes were elicited as yet. An x-ray film of* hand and wrist showed the bone age to be only about 6 months, i.e. significantly retarded.

This boy started to walk freely at 1 / years and said the first words with meaning at 21 months. A years his behavioral development was at a level of about 18 months according to the Gesell schedule, though lower in language development and toilet control. He still had mild alternating esotropia. He tended to hold his mouth open, without excessiv drooling. He was still somewhat hypotonic and *the tendon reflexes remained absent.*

During the following 8 months he gained 4 kg and began to be obese. Many teeth were becoming carious. *He had lax joints, pes planus and mild genu valgum.* At 2 years 8 months the penis measured 4 cm in length, and the testes remained impalpable. There were flickers f knee jerks but no other definite tendon reflexes, though power was now fair

This boy became significantly overweight at about 3 years. Eight months later he had a significantly low *bone age f still only about 2 years. When last seen at* 5 years 8 months he weighed 72 lb (32.7 kg), i nearly +6 SD for his age while the height of 111 cm was slightly below the mean (Fig. 18). The head circumference of 55 / cm had become significantly big for the age (+3 SD). The pinnae were primitive in shape. There was marked truncal obesity with delicate small hands and feet. *The joints remained rather lax. H had bilateral* gen valgum with an intermalleolar distance of 10 cm.

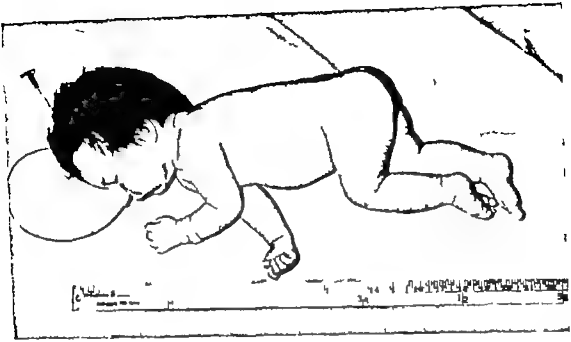

Fig. 16 Case 5 At 6 weeks the infant is lying limply on his side nasogastric tube is used for feeding.

His speech as poorly articulated. He showed some perseveration in his behaviour Gesell testing suggested that he as mildly retarded (D Q about 60). X-ray films of the left arm showed normal-sized muscle mass with excessive subcutaneous fat. The bone age was now about 4 years and thus no longer significantly low Glucose and cortisone-glucose tolerance tests were normal. This boy and brother were shown to have significant amounts of synalbumin antagonist to insulin in their plasma (see Table 6)

Case 6

R S. is the fourth of 5 children His older siblings are all married and have normal children younger brother is healthy and still at home. The father is reported to be healthy farmer The mother has migraine and is described as anxious but genuinely fond of the patient. A maternal aunt had epilepsy but is said to have outgrown it, one of her children is reported to be severely retarded, allegedly from birth injury The pregnancy ith our patient was evidently normal initially but at about 4 months gestation the family home was destroyed by fire and the mother as greatly upset. Subsequently she felt hardly any fetal movements. Labor occurred at term and lasted about 6 hours, anesthetic as used. At birth the infant weighed only 2268 g and was so limp that he was not expected to survive. According to his mother he "did not le for 2 months and just lay silent in his crib without movement He as thin and took feedings very slowly He only regained his birth weight after more than 6 week H testicles were noted to be undescended His mother states that he only gave his first cry after one year and three days. It is said that he could not walk until the age of 2 and did not learn to talk until the age of 6 years. He was good-natured and friendly At years

Fig. 17 Case 5 Facies at 1 year

The boy and brother were shown to have significant amounts of synalbumin antagonist to insulin in their plasma (see Table 6)

Case 6

R S is the fourth of 5 children. His older siblings are all married and have normal children, younger brother healthy and still at home. The father is reported to be healthy farmer The mother has migraines and is described as nervous but extremely fond of the patient A maternal aunt had epilepsy but is said to have outgrown one of her children reported to be severely retarded, allegedly from birth injury The pregnancy with our patient was evidently normal initially but at about 4 months gestation the family home was destroyed by fire and the mother was greatly upset. Subsequently she felt hardly any fetal movements. Labor occurred at term and lasted about 6 hours, anesthetic was used. At birth the infant weighed only 2268 g and was so limp that he was not expected to survive According to his mother he did not wake for 2 months and just lay silent in his crib without movement. He was thin and took feedings very slowly He only regained his birth weight after more than 6 weeks His testicles were noted to be undescended. His mother states that he only gave his first cry after one year and three days. It is said that he could not walk until the age of 2 and did not learn to talk until the age of 6 years. He was good-natured and friendly At 2 years

Fig 17 Case 5 Facies at 1 year

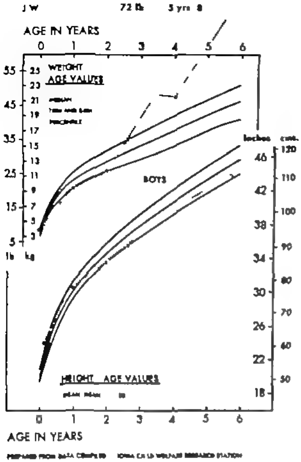

Fig 18. Case 5 Growth chart. *After the first 2 years the weight rises sharply while the height remains low*

he became very fat. After 3 years he had a tremendous appetite and gradually became more difficult to handle.

At 8 years 3 months he weighed 47 6 kg when he was admitted temporarily to the Provincial Mental Hospital. He was described as a very obese fair-haired boy with cheerful expression but inclined to temper tantrums. The penis and scrotum were small, and no testicles were palpable. The Stanford-Binet (Form L) test indicated an I.Q of 40. His highest scores were in comprehension, while the first failures came in recognizing pictorial representations. His enunciation was very poo He walked slowly and with waddling gait. Laboratory investigations were essentially negative (Table 3)

One month later he was transferred to the Woodlands School for the retarded. Despite the use of amphetamine he continued to gain weight. Androgen was also administered. Caries was noted in his deciduous teeth. At 11 years he weighed 91 kg. The head circumference was significantly large (56 / cm, i.e. +3 SD). The penis measured only about 5 cm after years of androgen therapy but acne and the presence of facial, axillary and pubic hair were noted. Glucose and insulin tolerance tests were normal. Androgen therapy was discontinued. At nearly 13 years the boy was discharged home, and 2 years later the family had managed to reduce the weight to 63.5 kg.

At 20 years this patient was re-admitted temporarily to the provincial school for the retarded. He was reported to help on the family farm but had not learned to read or write He had reddish-blond hair and marked truncal obesity (Fig. 19). His height of 160 cm was significantly small, whereas his weight of 100 kg was significantly high for his age and 5 SD above the mean for his height-age. He had Brushfield spots on the irides. The teeth were poorly aligned, with many fillings. The palate was slightly arched. The heart and peripheral pulses were unremarkable, blood pressure 140/80. The penis measured about 7 cm in length and was largely embedded in fat; the testes remained undescended. Pubic hair showed female distribution (Fig. 20) The hands and feet were relatively small and graceful. The right hand showed a transverse palm crease, and both little fingers were slightly incurved. The toenails were small and somewhat curved, and the nails of the little toes were particularly short.

The lad appeared left-handed. He talked mostly in short sentences, with poor articulation, especially for *th-* and *l-*sounds. The eye movements were full, with slight overaction of the right inferior oblique muscle. Hyperopic astigmatism was suspected. Tone and power appeared generally normal and the tendon reflexes wer all present symmetrically (+ ?). Coordination was only fair and he was unable to hop on either foot but did perform tandem gait.

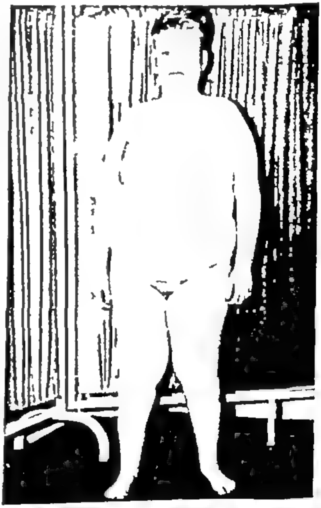

Fig 19 Case 6. At 20 years the obesity affects chiefly the trunk and thighs.

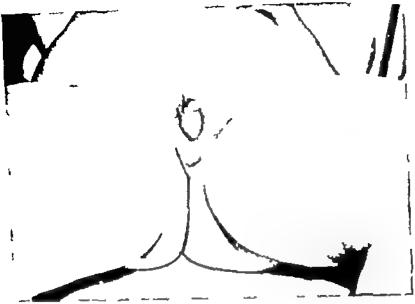

Fig. 20. Case 6. External genitalia at 20 years. The penis is small; the testes are undescended; scanty pubic hair has female distribution.

Psychometric assessment demonstrated particular intellectual dysfunction in visual-perceptual abilities. In his attempts to draw man, or to reproduce digit symbols in the Bender Gestalt test, the patient showed that his ability to reproduce forms as only at the level of 4 to 5 years. His oral verbal abilities were relatively highly developed, with verbal I.Q. of 46 on the Wechsler Adult Intelligence Scale. His social abilities seemed to make the most of his intellectual potential and were rated as S.Q. 32 on the Vineland Social Maturity Scale.

Glucose and cortisone-glucose tolerance tests showed high curves within normal limits. X-ray examination of elbows and knees showed normal skeletal maturity. The urinary 17-ketosteroids ere 13.6 mg and urinary FSH between 6 and 16 mouse units per 24 hours and thus within the normal range.

Case 7

P.D. was an infant of 1 year, the third child in his family. The parents and siblings were healthy. The pregnancy as normal, but the baby did not seem as active as the others had been. Two weeks before delivery there appeared to be breech presentation, but the infant turned spontaneously. Labor occurred normally ten days after term; the birth weight was 2992 g. The infant had very weak cry and had to be tube-fed. The mother, registered nurse, took him home after one week and continued gavaging for 2 months. He then began to suck more strongly, but did not move much and perspired easily. He smiled at 4 weeks, but did not move his hands to his mouth until the age of 6 weeks. At 6 months he began to raise his head prone, and at 10 months he began to roll over. The first teeth erupted at 11 / months.

At 1 year he was still unable to remain sitting or to say any words. He lay limply in the frog position and had pleasant but dull facial features and dark-blond hair (Fig. 21). His length was normal (79 cm), weight 9270 g. Acromicria was noted, with tapering of the distal finger phalanges and small toenails. The dental enamel was hypoplastic. The testes were undescended, prepuce phimotic. The eye movements appeared normal. There was marked general hypotonia, and the tendon reflexes were barely obtainable. X-ray examination showed slender long bones, ith bone age of only 7 months at the hand and wrist. The chromosomal karyotype proved normal. Glucose and hydrocortisone-glucose tolerance tests gave notably divergent curves, but the latter curve was not distinctly diabetic. The results of other investigations are listed in Table 3.

Case 8

P.F., the second girl in this series, is the second of 5 children in her family. The mother first pregnancy had ended in the birth of an anencephalic monster. Otherwise the family history was non-contributory apart from allergies, including asthma. During this second pregnancy the mother had three episodes of slight bleeding during the first trimester. The fetal movements appeared normal. Delivery occurred normally about 4 weeks after term; the birth weight was 2948 g. The infant wa very weak and barely able to take breast feedings. She was discharged home after one week. A week later she was re admitted to hospital after two cyanotic episodes, and her eyes were found to be turned in. She was then markedly listless and hypotonic and kept in an oxygen tent. At 6 weeks neurosurgeon performed pneumoencephalogram, hich revealed only moderate dilatation of the 3rd and lateral ventricles. A neurologist made diagnosis of amyotonia congenita. At 2 / months pilonidal cyst was removed.

Subsequently she only learned to remain sitting at 13 months and walked freely at 23 months. At 14 months she was again seen in neurological consultation and was

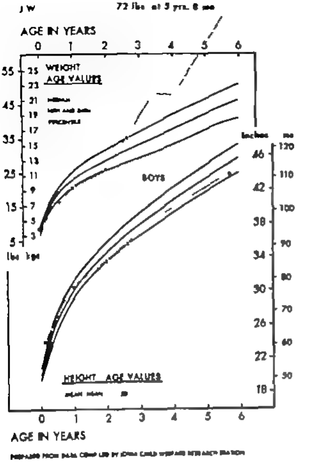

Fig 18 Case 5 Growth chart. After the first 2 years the weight rises sharply while the height remains low

he became very fat. After 3 years he had a tremendous appetite and gradually became more difficult to handle

At 8 years 3 months he weighed 47 6 kg when he was admitted temporarily to the Provincial Mental Hospital. He was described as a very obese fair-haired boy with cheerful expression but inclined to temper tantrums. The penis and scrotum were small, and no testicles were palpable. The Stanford–Binet (Form L) test indicated an I.Q of 40. His highest scores were in comprehension, while the first failures came in recognizing pictorial representations. His enunciation was very poor He walked slowly and with waddling gait. Laboratory investigations were essentially negative (Table 3).

he became very fat. After 3 years he had a tremendous appetite and gradually became more difficult to handle.

At 8 years 3 months he weighed 47.6 kg when he was admitted temporarily to the Provincial Mental Hospital. He was described as a very obese fair-haired boy with cheerful expression but inclined to temper tantrums. The penis and scrotum were small, and no testicles were palpable. The Stanford-Binet (Form L) test indicated an I.Q. of 40. His highest scores were in comprehension, while the first failures came in recognizing pictorial representations. His enunciation was very poor. He walked slowly and with waddling gait. Laboratory investigations were essentially negative (Table 3)

One month later he was transferred to the Woodlands School for the retarded. Despite the use of amphetamine he continued to gain weight. Androgen was also administered. Caries was noted in his deciduous teeth. At 11 years he weighed 91 kg. The head circumference was significantly large (56 / cm, i.e. +3 SD) The penis measured only about 5 cm after 2 years of androgen therapy but acne and the presence of facial, axillary and pubic hair were noted. Glucose and insulin tolerance tests were normal. Androgen therapy was discontinued. At nearly 13 years the boy was discharged home, and _ years later the family had managed to reduce the weight to 63.5 kg.

At 20 years this patient was re-admitted temporarily to the provincial school for the retarded. He was reported to help on the family farm but had not learned to read or write. He had reddish-blond hair and marked truncal obesity (Fig. 19). His height of 160 cm was significantly small, whereas his weight of 100 kg was significantly high for his age and 3 SD above the mean for his height-age. He had Brushfield spots on the irides. The teeth were poorly aligned, with many fillings. The palate was slightly arched. The heart and peripheral pulses were unremarkable, blood pressure 140/80. The penis measured about 7 cm in length and was largely embedded in fat; the testes remained undescended. Pubic hair showed female distribution (Fig. 20). The hands and feet were relatively small and graceful. The right hand showed a transverse palm crease and both little fingers were slightly incurved. The toenails were small and somewhat curved, and the nails of the little toes were particularly short.

The lad appeared left-handed. He talked mostly in short sentences, with poor articulation, especially for *th*- and *l*-sounds. The eye movements were full, with slight overaction of the right inferior oblique muscle. Hyperopic astigmatism was suspected. Tone and power appeared generally normal and the tendon reflexes were all present symmetrically (+). Coordination was only fair and he was unable to hop on either foot but did perform tandem gait.

Fig 19 Case 6. At 20 years the obesity affects chiefly the trunk and thighs.

and appeared small and fibrotic. Two and one-half hours after birth pediatrician found the baby limp and almost motionless, without Moro response or palmar grasp. A blood smear showed plentiful platelets. With tube feedings and incubator care the infant's condition improved only slowly. He developed bilateral cephalhematomata. Three weeks after birth he began to gain weight, and the Moro and palmar grasp responses could be elicited. On discharge home at 7 weeks he still "just lay" and was difficult to feed.

Subsequently he only remained sitting and said the first words at 14 months. The mother said his teeth "looked beautiful, white and even, but quickly decayed." She appears to have rejected this boy emotionally perhaps because she had been told initially that he was brain-damaged and might not survive. At 3 years he was recommended for admission to the provincial residential school for the retarded, since the mother became increasingly nervous. She complained that he seemed hungry and cried all night but never gained. At 4 years he was admitted temporarily to the residential school. He was then significantly small (89 cm, i.e. minus over 4 SD) and

Fig. 22 Case 9 Patient at 9 years, showing obesity of trunk and thighs, significantly small stature, mild genu valgum and underdeveloped genitalia.

Fig. — Case 8 Patient at 13 years, showing obesity of trunk and thighs, significantly small stature, mild genu valgum, and distension striae on lower abdomen.

weighed 15.9 kg. The head circumference was normal. Numerous bruises were noted. His teeth were carious. He had left esotropia and flat-footed, broad-based gait. The bone age was only 2 years (5 SD). An EEG showed activity at 7–9 cycles per second, with considerable hypsynchronous spike activity particularly in the occipital leads.

When he was discharged home it was recommended that he should be placed in foster family but this was not accomplished until he was 7 years old. According to the foster mother he only weighed 15 kg at that time and was unable to talk in sentences. Under her affectionate care he gained no less than 50 lb (22.7 kg) in years. At 8 he was considered to have Stanford-Binet I.Q. of about 30.

When seen at 9 years he presented as dull and obese boy with somewhat pigmented skin suggestive of partly American-Indian origin (Fig. 22). His height of 118 cm was nearly 4 SD below the mean for white boys, while his weight of 40 kg was 6 SD above the mean for

Fig 21 Case 7 At 1 year the boy lies limply has pleasant features and dark-blond hair

considered alert and interested, with improving tone and power She said the first words with meaning at about years. She also developed marked caries, and all the deciduous incisors and canines were removed at 3 years. Subsequently she began to have asthmatic attacks.

At 4 years she weighed only 12.2 kg, but by the age of 6 she was becoming significantly obese and weighed 22.2 kg. At that time she was noted to be clumsy and rather passive her articulation was poor and she tired easily An alternating strabismus was evident. She was still somewhat hypotonic, unable to hop and awkward in attempting to run. Her gait was waddling. The plantar responses were equivocal. At a Child Guidance Clinic she was assessed as having a mental age of 4 years 11 months at a chronological age of 6 years 2 months. She was kept in kindergarten for an extra year and when she started school at 6 years 9 months she was found to be unready and had to repeat Grade 1 After that she attended special classes. At 12 years a psychometric assessment showed her to have a full scale I.Q of 56 on the W.I.S.C. (verbal scale 65 performance 54) On the Peabody Picture Vocabulary Test she attained an I.Q of 66, whereas she only received a minimal I Q score of 46 on the Draw-a-Man test.

When seen at 13 / years she was a pleasant, obese girl with somewhat dull features, brown hair bluish-grey irides and small hands and feet. She was significantly small for her age (142 cm, i.e −3 SD) but weighed 65.4 kg, which was 4 SD above the mean for her height age. The permanent teeth showed moderat caries. The palate was somewhat narrow and arched. The pinnae were poorly modelled. The menarche had not yet occurred but she had moderate mammary development, pubic and axillary hair (Fig. 22). The fat was chiefly deposited on the trunk and proximal part of the limbs, and pinkish-mauve distension striae were noted on the breasts and lower abdomen and over the buttocks. She also had mild genu valgum, xcessive lumbar lordosis, lax joints and flat feet. There was mild left esotropia. She still exhibited moderate generalized hypotonia with fair power and sluggish tendon reflexes. Choreiform mo ements were observed in the outstretched hands The presence of general clumsiness and poor hopping and of equivocal plantar and Chaddock responses was confirmed.

The oral glucose tolerance test (1 75 g per kg body weight) showed a diabetic curve (Fig. 26), while an insulin sensitivity test proved normal. In an insulin-glucose tolerance test, using 1 g of glucose per kg body weight, a diabetic response was noted again. The EEG showed low voltage irregular fast activity in all head regions, without focal or epileptiform abnormality hyperventilation produced rhythmic 9 to 11 per second activity in both posterior head regions in addition to some intermediate slow activity The buccal smear showed chromatin-positive cells. The chromosomal karyotype was normal female. The remaining i vestigations are listed in Tables 3 4 5 and 7

Case 9

E.H. is the 3rd of 5 children, and the mother also had a miscarriage and a stillbirth. The siblings are healthy The father and paternal grandfather developed impaired hearing after the age of about 30 years. The father and mother are otherwise healthy though the latter describes herself as nervous. A maternal uncle is reported to be very small person he is the only survivor of twins, the othe having died malformed at birth. The pregnancy with our patient was uneventful, and fetal movements were felt normally However the membranes ruptured spontaneously a month before term, and the infant was born the same day after labor lasting 6 hours. He weighed only 2240 g and wa cyanosed and slow to breathe. H also showed multiple petechiae. The scrotum was small and empty The placenta had to be removed manually

and appeared small and fibrotic. Two and one-half hours after birth a pediatrician found the baby limp and almost motionless, without Moro response or palmar grasp. A blood smear showed plentiful platelets. With tube feedings and incubator care the infant's condition improved only slowly. He developed bilateral cephalhematomata. Three weeks after birth he began to gain weight, and the Moro and palmar grasp responses could be elicited. On discharge home at 7 weeks he still "just lay" and was difficult to feed.

Subsequently he only remained sitting and said the first words at 14 months. The mother said his teeth "looked beautiful, like and even, but quickly decayed" She appears to have rejected this boy emotionally perhaps because she had been told bluntly that he was brain-damaged and might not survive. At 3 years he was recommended for admission to the provincial residential school for the retarded, since the mother became increasingly nervous. She complained that he seemed hungry and cried all night but never gained. At 4 years he was admitted temporarily to the residential school. He was then significantly small (89 cm, i.e. minus over 4 SD) and

weighed 15.9 kg. The head circumference was normal. Numerous bruises were noted. His teeth were carious. H had left esotropia and flat-footed, broad based gait. The bone age was only 2 years (−5 SD). An EEG showed activity at 7–9 cycles per second, with considerable basynchronous spike activity particularly in the occipital leads.

When he was discharged home it was recommended that he should be placed in foster family but this was not accomplished until he was 7 years old. According to the foster mother he only weighed 15 kg at that time and was unable to talk in sentences. Under her affectionate care he gained no less than 50 lb (22.7 kg) in 2 years. At 8 / he as considered to have Stanford–Binet I Q of about 30.

When seen at 9 / years he presented as doll and obese boy with somewhat pigmented skin suggestive of partly American-Indian origin (Fig. 23). His height of 118 cm was nearly 4 SD below the mean for white boys, but his weight of 40 kg was 6 SD above the mean for

Fig 21 Case 7 At 1 year the boy lies limply has pleasant features and dark-blond hair

considered alert and interested, with improving tone and power She said the first words with meaning at about years. She also developed marked caries, and all the deciduous incisors and canines were removed at 3 years. Subsequently she began to have asthmatic attacks.

At 4 years she weighed only 12.2 kg, but by the age of 6 she was becoming significantly obese and weighed 22… kg. At that time she was noted to be clumsy and rather passive her articulation was poor and she tired easily An alternating strabismus was evident. She was still somewhat hypotonic, unable to hop and awkward in attempting to run. Her gait was waddling. The plantar responses were equivocal. At a Child Guidance Clinic she was assessed as having a mental age of 4 years 11 months at a chronological age of 6 years 2 months. She was kept in kindergarten for an extra year and when she started school at 6 years 9 months she was found to be unready and had to repeat Grade 1 After that she attended special classes. At 1 years a psychometric assessment showed her to have a full scale I Q of 56 on the W.I.S.C (verbal scale 6? performance 54). On the Peabody Picture Vocabulary Test she attained an I.Q f 66, whereas she only received a minimal I Q score of 46 on the Draw-a-Man test.

When seen at 13 years she was a pleasant, obese g l with somewhat dull features, brown hair bluish-grey irides and small hands and feet. She was significantly small for her age (14? cm, i e −3 SD) but weighed 65.4 kg, which was 4 SD above the mean for her height age The permanent teeth showed moderate caries. The palate was somewhat narrow and arched. The pinnae were poorly modelled. The menarche had not yet occurred but she had moderate mammary development, pubic and axillary hair (Fig 22) The fat was chiefly deposited on the trunk and proximal part of the limbs, and pinkish-mauve distension striae were noted on the breasts and lower abdomen and over the buttocks. She also had mild genu valgum, excessive lumbar lordosis, lax joints and flat feet. There was mild left esotropia. She still exhibited moderate generalized hypotonia with fair power and sluggish tendon reflexes. Choreiform movements were observed in the outstretched hands. The presence of general clumsiness and poor hopping and of equivocal plantar and Chaddock responses was confirmed.

The oral glucose tolerance test (1 75 g per kg body weight) showed a diabetic curve (Fig. 26), while an insulin sensitivity test proved normal. In an insulin-glucose tolerance test, using 1 g of glucose per kg body weight, a diabetic response was noted again. The EEG showed low-voltage irregular fast activity in all head regions, without focal or epileptiform abnormality hyperventilation produced rhythmic 9 to 11 per second activity in both posterior head regions in addition to some intermediate slow activity The buccal smear showed chromatin-positive cells. The chromosomal karyotype was normal female. The remaining investigations are listed in Tables 3 4 5 and 7

Case 9

E.H. is the 3rd of 5 children, and the mother also had a miscarriage and a stillbirth. The siblings are healthy The father and paternal grandfather developed impaired hearing after the age of about 30 years. The father and mother are otherwise healthy though the latter describes herself as nervous. A maternal uncle is reported to be a very small person he is the only survivor of t ins, the other having died malformed at birth. The pregnancy with our patient was uneventful, and fetal movements were felt normally However the membranes ruptured spontaneously month before term, and the infant was born the same day after labor lasting 6 hours. H weighed only 2240 g and was cyanosed and slow to breathe. He also showed multiple petechiae. The scrotum wa small and empty The placenta had to be removed manually

and appeared small and fibrotic. Two and one-half hours after birth pediatrician found the baby limp and almost motionless, without Moro response or palmar grasp. A blood smear showed plentiful platelets. With tube feedings and incubator care the infant's condition improved only slowly. He developed bilateral cephalhematomata. Three weeks after birth he began to gain weight, and the Moro and palmar grasp responses could be elicited. On discharge home at 7 weeks he still "just lay" and was difficult to feed.

Subsequently he only remained sitting and said the first words at 14 months. The mother said his teeth "looked beautiful, late and even, but quickly decayed." She appears to have rejected this boy emotionally perhaps because she had been told initially that he was brain-damaged and might not survive. At 3 years he was recommended for admission to the provincial residential school for the retarded, since the mother became increasingly nervous. She complained that he seemed hungry and cried all night but never gained. At 4 years he was admitted temporarily to the residential school. He was then significantly small (89 cm, mean over 4 SD) and

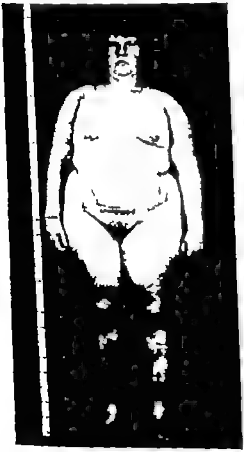

Fig. 22. Case 8. Patient at 13 / years, showing obesity of trunk and thighs, significantly small stature, mild genu valgum, and distension striae on lower abdomen.

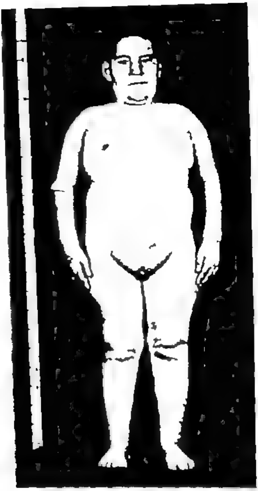

Fig. 23. Case 9. Patient at 9 / years, showing obesity of trunk and thighs, significantly small stature, mild genu valgum and underdeveloped genitalia.

weighed 15.9 kg. The head circumference was normal. Numerous bruises were noted. His teeth were carious. He had left esotropia and flat-footed, broad-based gait. The bone age was only 2 years (–5 SD). An EEG showed activity at 7-9 cycles per second, with considerable basynchronous spike activity particularly in the occipital leads.

When he was discharged home it was recommended that he should be placed in foster family but this was not accomplished until he was 7 years old. According to the foster mother he only weighed 15 kg at that time and was unable to talk in sentences. Under her affectionate care he gained no less than 50 lb (22.7 kg) in 2 / years. At 8 / he was considered to have a Stanford–Binet I.Q. of about 30.

When seen at 9 / years he presented as a dull and obese boy with somewhat pigmented skin suggestive of partly American-Indian origin (Fig. 23). His height of 118 cm was nearly 4 SD below the mean for white boys, while his weight of 40 kg was 6 SD above the mean for

Fig 24 Case 9 Facies at 9 / years, with mild left esotropia. The skin is somewhat pigmented, hair brown.

his height-age. The head circumference remained normal. The palate was slightly arched. Many teeth showed caries on hypoplastic enamel. The pinnae were primitive in shape. Both hands and feet were small. The palms were somewhat flat, with marked creasing, and there was partial syndactyly of the 2nd and 3rd toes. He also had mild genu valgum. The penis was small and circumcised, with some prepuce still partially adherent to the glans. The scrotum was small and pigmented the testes were not palpable. The prostate was felt on rectal examination. The boy formed only short sentences and was unable to print or read. His speech was poorly articulated. Mild left esotropia persisted (Fig. 4) The trunk and limbs were still somewhat hypotonic, with fair power sluggish tendon reflexes and broad-based, flat-footed gait.

A further EEG now showed no definite abnormality The bone age at hand and wrist was nearly 8 years and thus just significantly low while skull x-rays showed no abnormality The buccal smear was chromatin-negative. The chromosomal karyotype was normal except for a "long Y" as in Case 3 The 4-hour urinary excretion f 17-ketogenic steroids rose from 4 4 and 3.6 mg to 14.2 mg after administration of 2500 mg f metyrapone in divided doses over 24 hours. Glucose and cortisone-glucose tolerance tests both gave somewhat high curves, but neither were definitely indicative of diabetes by the criteria of Fajans and Conn (17) A blood count showed a hemoglobin concentration of only 11 g/100 ml, with moderate anisocytosis, and the serum iron level was 53 μg/100 ml, with a total iron-binding capacity of 446 μg/100 ml, giving a percent saturation of only 12% Other investigations are listed in Tables 3, 4 5 and 7

ANALYSIS OF CLINICAL FEATURES

Sex and age

Seven of our 9 patients are males. This male predominance corresponds to that in other series, but does not necessarily imply that the syndrome is commoner in boys, since it may be merely a reflection of the fact that the hypogenitalism is a more obvious diagnostic feature in males. The ages of our patients vary from infancy to 20 years, and it has been of interest to follow the progess of 4 children (Cases 1 2, 3 and 5) from shortly after birth for 5 to 8 years.

Family history

In these 9 patients the parents are mostly healthy None of them is consanguineous. One mother had glycosuria during pregnancy and one father (and the paternal grandfather) developed impaired hearing after the age of 30 years. Of 8 mothers, concerning whom the information was available, 3 had had 5 2 and 1 miscarriages, respectively and the third had also had a stillbirth (see Table 1). Another of these 8 mothers (Case 8) had given birth to an anencephalic monster prior to the pregnancy with our patient. Two others of this group of mothers (Cases 3 and 5) had gaps of 14 and 17 years, respectively between the previous pregnancy and that with our patient.

Apart from the mother with glycosuria, there is an instance where the maternal grandmother was a diabetic; the other children have no family history of diabetes. Nor is obesity a feature in these families merely one boy has a plump elder brother whose testes only came down after hormone treatment. Mental retardation is reported only in more distant relatives thus the male adult (Case 6) has an epileptic maternal aunt with a retarded child and in Case 4 the mother has a maternal half aunt who is described as mentally slow

A maternal uncle of Case 1 is reported to have taken feedings poorly after birth and to have died at 3 months, but the nature of his disease is obscure A paternal uncle of Case 2 died at 3–4 months after incision of an abscess. A maternal uncle of Case 9 also died in infancy probably owing to congenital malformations.

Parental age

The average age of the fathers at the time of the child's birth was 35 (range 27 to 45) and that of the mothers 33 [illegible] (range 25 to 42) years. The mean maternal age of all live births in the Province of British Columbia in 1955–60 was only 27.0 years, and the mean maternal age of 33.6 years in our series thus would appear to be distinctly higher and also very close to the mean maternal age at the birth of mongoloid children in British Columbia, which was 33.7 years in 1955–60 (52). However, this finding is divergent from that in other series of the Prader–Labhart–Willi (PLW) syndrome. From data kindly supplied by Professor C. Hooft (Gent, Belgium), Dr P. R. Evans (London, England), Dr B. Laurence (Derby, England) and Dr D. Hoefnagel (Hanover, N. H., U.S.A.) the mean paternal age of 18 other patients is calculated as 29.2 (range [illegible] to 40) and the mean maternal age as 27.1 (range 20 to 34) years, and thus both appear to be within the normal range. This discrepancy from our own finding is unexplained. If the parental ages of our 9 patients are added to those of the other 18 cases, we obtain a mean paternal age of 31.1 years and a mean maternal age of 29.3 years for the total 27 patients. As might be expected the mean birth order in our cases is also somewhat high, namely 3.7, as contrasted to 2.3 in Evans' (16) series.

Pregnancy and delivery

The pregnancy was usually unremarkable, though 4 of the 9 mothers had slight vaginal bleeding in the first trimester. In 5 cases the mother considered the fetal movements to be less than normal (Tables 1 and 2), but in one case the mother actually thought that the movements were excessive at times. Two babies (Cases 1 and 4) were born by breech presentation, while a third underwent spontaneous cephalic version prior to delivery (Case 7). One of the babies with breech presentation (Case 4) and two of the others (Cases 2 and 3) showed signs of fetal distress during labor and in Case 2 this led to Cesarean section. Of the 9 infants 4 showed marked asphyxia neonatorum, and another 3 were moderately affected. All these were resuscitated promptly and then breathed quite well, but remained limp. In at least 2 cases (No. 3 and 9) the placenta was noted to be infarcted or fibrotic. The mean birth weight was 2834 g and thus less than 3000 g, as noted by Prader and Willi (49), even though 7 of our 9 patients were born at or after term (see Table 1).

Physical findings

These are listed in Table 2. It will be noted that amyotonia, i.e. congenital hypotonia without evidence of a primary lesion in the lower motor neurone or muscle, was a universal finding in these patients during infancy. Similarly all children had acromicria, though this may be hard to determine with certainty in infancy, and all the boys had undescended testes and a small scrotum. Ultimately all the children also became obese and significantly overweight, but this usually happened after infancy (see Table 1). The mean weight at the age of 3 years was $5^1/_2$ SD above the mean for the height-age. The fat was distributed chiefly on the trunk and proximal part of the limbs.

With the exception of Case 7 (the infant of 1 year) all the children were below average in stature, but only 3 were smaller than -2 SD (more than 2 SD below the mean for their age). The head circumference was usually normal (mean for age ± 2 SD), in 2 patients (Case 5 and 6) it was just significantly large ($+2$ to 3 SD). In the 4 cases in which the time of closure of the anterior fontanelle was known, it was delayed beyond the age of 18 months. Dentition also tended to be delayed. Caries was usually marked in the deciduous teeth, and in 4 of 6 children it appeared to supervene on enamel hypoplasia. One boy (Case 2) who had received fluoride supplement orally did not develop caries like the others, but in another case (No. 5) the administration of fluoride did not prevent the tooth decay.

The younger children had somewhat characteristic, attractive facial features with a delicate mouth, high forehead, blue eyes and fair or auburn hair (see Cases 1 to 5 and 7). Later the features may become coarse and the hair may darken.

Phimosis was present in 4 of 5 boys who had not been circumcised. The penis did not usually appear significantly small in the first year of life, wheras the scrotum was distinctly small (and empty) even at birth. Later the penile size appeared subnormal, even if allowance was made for the suprapubic fat. The prostate gland was palpable rectally.

With regard to the hypotonia it may be noted that the tendon reflexes were initially absent in

Fig 24 Case 9 Facies at 9 / years, with mild left esotropia. The skin is somewhat pigmented, hair brown.

his height-age. The head circumference remained normal. The palate was slightly arched. Many teeth showed caries on hypoplastic enamel. The pinnae were primitive in shape. Both hands and feet were small. The palms were somewhat flat, with marked creasing, and there was partial syndactyly of the 2nd and 3rd toes. He also had mild genu valgum. The penis was small and circumcised, with some prepuce still partially adherent to the glans. The scrotum was small and pigmented the testes were not palpable. The prostate was felt on rectal examination The boy formed only short sentences and was unable to print o read. His speech was poorly articulated. Mild left esotropia persisted (Fig. 24). The trunk and limbs were still somewhat hypotonic with fair power sluggish tendon reflexes and broad-based, flat footed gait.

A further EEG now showed no definite abnormality The bone age at hand and wrist was nearly 8 years and *thus just significantly low while skull x-rays showed no* abnormality The buccal smear was chromatin-negative. The chromosomal karyotype was normal except for a "long Y" as in Case 3 The 24-hour urinary xcretion of 17-ketogenic steroids rose from 4 4 and 3 6 mg to 14.2 mg after administration of 2500 mg of metyrapone in divided doses over 24 hours. Glucose and cortisone-glucose tolerance tests both gave somewhat high curves, but neither were *definitely indicative f diabetes by the* criteria of Fajans and Conn (17). A blood count showed a hemoglobin concentration of only 11 g/100 ml, with moderate anisocytosis, and the serum iron level was 53 μg/100 ml, with a total iron-binding capacity of 446 g/100 ml, giving a percent saturation of only 12% Other investigations are listed in Tables 3 4, 5 and 7

ANALYSIS OF CLINICAL FEATURES

Sex and age

Seven of our 9 patients are males. This male predominance corresponds to that in other series, but does not necessarily imply that the syndrome is commoner in boys, since it may be merely a reflection of the fact that the hypogenitalism is a more obvious diagnostic feature in males. The ages of our patients vary from infancy to 20 years and it has been of interest to follow the progess of 4 children (Cases 1 2 3 and 5) from shortly after birth for 5 to 8 years.

Family history

In these 9 patients the parents are mostly healthy None of them is consanguineous. One mother had glycosuria during pregnancy and one father (and the paternal grandfather) developed impaired hearing after the age of 30 years. Of 8 mothers, concerning whom the information was available, 3 had had 5 2 and 1 miscarriages, respectively and the third had also had a stillbirth (see Table 1) Another of these 8 mothers (Case 8) had given birth to an anencephalic monster prior to the pregnancy with our patient. Two others of this group of mothers (Cases 3 and 5) had gaps of 14 and 17 years, respectively between the previous pregnancy and that with our patient.

Apart from the mother with glycosuria, there is an instance where the maternal grandmother was a diabetic; ■ other children have no family history of diabetes. Nor is obesity a feature in these families merely one boy has a plump elder brother whose testes only came down after hormone treatment. Mental retardation is reported only in more distant relatives thus the male adult (Case 6) has an epileptic maternal aunt with a retarded child and in Case 4 the mother has a maternal half aunt who is described as mentally slow

A maternal uncle of Case 1 is reported to have taken feedings poorly after birth and to have died at 3 months, but the nature of his disease is obscure. A paternal uncle of Case 2 died at 3–4 months after incision of an abscess. A maternal uncle of Case 9 also died in infancy probably owing to congenital malformations.

Parental age

The average age of the fathers at the time of the child's birth was 35 (range 27 to 45) and that of the mothers 33.6 (range 25 to 4) years. The mean maternal age of all live births in the Province of British Columbia in 1955–60 was only 27.0 years, and the mean maternal age of 33.6 years in our series thus would appear to be distinctly higher and also very also close to the mean maternal age at the birth of mongoloid children in British Columbia, which was 33 7 years in 1955–60 (52) However this finding is divergent from that in other series of the Prader–Labhart–Willi (PLW) syndrome. From data kindly supplied by Professor C. Hooft (Gent, Belgium), Dr. P. R. Evans (London, England), Dr B. Laurance (Derby England) and Dr D Hoefnagel (Hanover, N. H., U.S.A.) the mean paternal age of 18 other patients is calculated as 29.2 (range 22 to 40) and the mean maternal age as 27 1 (range 20 to 34) years, and thus both appear to be within the normal range. This discrepancy from our own finding is unexplained. If the parental ages of our 9 patients are added to those of the other 18 cases, we obtain a mean paternal age of 31 1 years and a mean maternal age of 29 3 years for the total 27 patients. As might be expected the mean birth order in our cases is also somewhat high, namely 3 7 as contrasted to 2.3 in Evans (16) series.

Pregnancy and delivery

The pregnancy was usually unremarkable, though 4 of the 9 mothers had slight vaginal bleeding in the first trimester In 5 cases the mother considered the fetal movements to be less than normal (Tables 1 and 2), but in one case the mother actually thought that the movements were excessive at times. Two babies (Cases 1 and 4) were born by breech presentation, while a third under went spontaneous cephalic version prior to delivery (Case 7). One of the babies with breech presentation (Case 4) and two of the others (Cases 2 and 3) showed signs of fetal distress during labor and in Case 2 this led to Cesarean section. Of the 9 infants 4 showed marked asphyxia neonatorum, and another 3 were moderately affected. All these were resuscitated promptly and then breathed quite well, but remained limp. In at least 2 cases (No. 3 and 9) the placenta was noted to be infarcted or fibrotic. The mean birth weight was 834 g and thus less than 3000 g, as noted by Prader and Willi (49) even though 7 of our 9 patients were born at or after term (see Table 1).

Physical findings

These are listed in Table _. It will be noted that amyotonia i.e. congenital hypotonia without evidence of a primary lesion in the lower motor neurone or muscle, was a universal finding in these patients during infancy Similarly all children had acromicria, though this may be hard to determine with certainty in infancy and all the boys had undescended testes and a small scrotum. Ultimately all the children also became obese and significantly overweight, but this usually happened after infancy (see Table 1). The mean weight at the age of 3 years was $5^1/_2$ SD above the mean for the height-age The fat was distributed chiefly on the trunk and proximal part of the limbs.

With the exception of Case 7 (the infant of 1 year) all the children were below average in stature, but only 3 were smaller than −2 SC (more than 2 SD below the mean for their age). The head circumference was usually normal (mean for age + SD) in 2 patients (Case 5 and 6) it was just significantly large (+2 to 3 SD). In the 4 cases in which the time of closure of the anterior fontanelle was known, it was delayed beyond the age of 18 months. Dentition also tended to be delayed. Caries was usually marked in the deciduous teeth, and in 4 of 6 children it appeared to supervene on enamel hypoplasia. One boy (Case 2) who had received fluoride supplement orally did not develop caries like the others, but in another case (No. 5) the administration of fluoride did not prevent the tooth decay

The younger children had somewhat characteristic, attractive facial features with a delicate mouth, high forehead, blue eyes and fair or auburn hair (see Cases 1 to 5 and 7). Later the features may become coarse and the hair may darken.

Phimosis was present in 4 of 5 boys who had not been circumcised. The penis did not usually appear significantly small in the first year of life, wheras the scrotum was distinctly small (and empty) even at birth. Later the penile size appeared subnormal, even if allowance was made for the suprapubic fat. The prostate gland was palpable rectally

With regard to the hypotonia it may be noted that the tendon reflexes were initially absent in

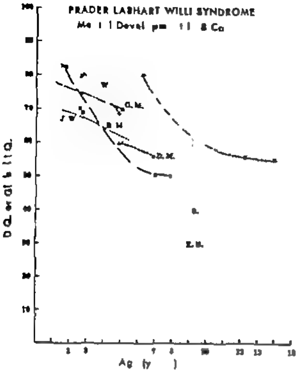

Fig. 15 Prader Labhart Willi syndrome. Mental development in 8 cases.

3 infants, whereas they were present though diminished in 3 others. *After the first year the* tendon reflexes could usually be elicited but they tended to remain sluggish (+1) at least until the second decade. Simultaneously muscle tone improved, but mild hypotonia usually remained, with some laxity of joints and pes planus.

Seven out of 9 children had either a definite squint or at least overaction of an inferior oblique muscle. In addition, there was a wide variety of minor congenital stigmata, particularly poor modelling of pinnae (Fig. 12), short toenails, and arched palate. *Two of our patients had narrow* external ear canals as in Down's syndrome, and bilateral *simian creases, clinodactyly* Brushfield spots on the irides, and mongoloid slanting of the palpebral fissures were also noted in 2 cases each.

Dermatoglyphic pattern

Dermatoglyphic analyses were carried out on all the patients by Dr J R. Miller and are presented in detail in appendix. There were no consistent striking aberrations in the dermal configurations.

The digital patterns were unremarkable with the exception of a relatively rare radial loop on the 3rd digit of the *left hand of Case 4* The average total ridge count of 112.8 was low (Canadian population 133.9 $\pm$1.6) Although this appears to be attributable largely to one patient (Case 2) it is of interest that all but one patient (Case 1) were below the average for their sex, and this point regarding ridge count should be clarified in a larger sample.

The palmar patterns appeared to show normal variations. There were no thenar+Int_1 or Int_2 patterns. Loop distal patterns occured in Int_3 and Int_4 with expected frequency. With the exception of one patient (Case 5) who had a A /W^x/A pattern, the hypothenar patterns were unremarkable. *Only one patient (Case 2) had a significant* displacement of the axial triradius (*atd* angle 59 ht 33.3%)

On the hallucal area the patterns were distal loops or whorls. There were no obvious aberrations in plantar patterns.

Development

The growth charts of Cases 1 to 5 demonstrate that the weight tended to be *below* the 16th percentile for at least the first year when the infant often presented feeding problems during the amyotonic phase. In the second or third year the weight rose and abnormal fat deposition on trunk and buttocks was often evident. If we exclude *Case 9 whose food intake may have been severely* restricted we see from Table 1 that the weight rose above the normal range (i.e. above +2 SD for the height-age) at ages varying from 2 to 6 years, with a mean of 3 years $1^1/_2$ months. In contrast, the stature sometimes tended to drop more below the mean *after* the first year (Cases 1 2 5), and growth did not accelerate notably with weight gain.

Table 1 also shows the delay in the passage of developmental milestones. The patients remained sitting freely *at 10 months to $1^1/_2$ years, with a* mean of 13 months, and they learned to walk *freely at 18 to 39 months*, with a mean of 25 months. They were reported to have said the first word with meaning at 10 to 24 months, with a mean of 16 months. Despite the delay in the acquisition of locomotor and language skills these children were usually alert and responsive particularly in their second and third years, and adaptive and *personal-social abilities were relatively* good. As in Down's syndrome the early developmental and even intellectual assessments often gave more hopeful results than later psychometric

tests. Fig. .5 demonstrates this relative downward trend in the D.Q. and I.Q. scores of 8 patients during the pre-school years. Thus the I.Q. level depends upon the age. In our 5 patients above the age of 6 years the latest global I.Q. assessment ranged from about 30 to 56 (Table 1).

INVESTIGATIONS

Radiological studies

X-ray examination of an arm was performed in all 9 patients (see Table 3). In 6 the bones and muscle bulk were both considered normal, but in 3 the long bones appeared slender and poorly mineralized, and in 2 of these the muscle masses were considered abnormally small. After infancy extensive soft fatty shadows were often evident. The *bone age* at the hand and wrist (22) was significantly retarded in all the 6 boys who were x rayed before the age of 4 years, but not in the one girl (Case 4). In two boys (Cases 3 and 5) the delay in the bone age was no longer significant (i.e. less than −2 SC) at 4 years 8 months and 5 years 8 months, respectively whereas in 2 others it was still significant at 8 and $9^1/_2$ years, respectively though to a lessened extent. In the adult male (Case 6) the elbow and knee showed mature bone development at 20 years. The older of the two girls also had a normal bone age at the wrist, hand, elbow and knee at 13 $/_2$ years.

Skull films were obtained in 6 of these children and were generally unremarkable apart from minor abnormalities of the vault in Cases 1 and 2. In the former at years 4 months, the anterior fontanelle was still open and the posterior fossa somewhat wide. In the latter at 1 year 9 months, the anterior fossa appeared somewhat narrow with unusually steep slope of its floor.

A pneumoencephalogram was only performed in one of our patients (Case 8) and proved normal apart from moderate dilatation of the 3rd and lateral ventricles. It was not considered justifiable to carry out this investigation in the other patients.

Electroencephalograms

These were recorded in 5 of our patients on one or more occasions. Each had at least one normal record, but Case 9 (who may have some superimposed brain damage from perinatal anoxia) had bisynchronous spike discharges at $4^1/_2$ years, mainly in the occipital leads, and Case 8 had low voltage irregular fast activity in all head regions as well as some alpha rhythm at $13^1/$ years.

Electromyograms, nerve conduction studies and muscle biopsies

The electromyogram in 4 and motor nerve conduction studies in 6 of our patients gave normal results for the age. Muscle biopsies were normal in 2 children, and in the third (Case 1) showed only somewhat small muscle fibers. In one of the children with a normal biopsy (Case 5) the motor end plates in the *deltoid* muscle were well impregnated with intravital methylene blue and were also shown to be normal. The lateral rectus muscle of the eye contained some fibrous tissue in Case 3.

Blood counts. Serology

Blood counts were normal in all patients except Case 9 who had a mild anemia, presumably due to iron deficiency. The VDRL serum precipitation or Kahn tests were uniformly negative.

Biochemical studies

Serum electrolyte and blood urea nitrogen levels and routine urinalyses were within normal limits in these patients. The serum cholesterol concentration was examined in 5 cases, and as shown in Table 3 the results were also essentially normal. The urinary amino-acids were checked by paper chromatography in 7 patients and were normal in pattern and quantity. The serum protein-bound iodine (PBI) concentration was slightly low (3.4 and 3.8 μg, respectively) in 2 children (Cases 1 and 4) during the second year but there was no clinical evidence of hypothyroidism. In 6 other patients the level of serum PBI was normal.

The urinary excretion of 17 ketosteroids was examined in 6 cases, and the results were within normal limits, though the values of 2.0 mg per 24 hours at 3 years 8 months and 3.32 mg per 24 hours at 4 $/_2$ years in Cases 1 and 3 respectively are both somewhat high. The urinary excretion of 17-ketogenic steroids was examined in 4 children and was unusually high at 9.2 and 6.81 mg per 4 hours, respectively in the same two boys (see 41).

The effect of metyrapone (40 and 50 mg per kg body weight, respectively in 6 divided doses over 24 hours) on the urinary excretion of

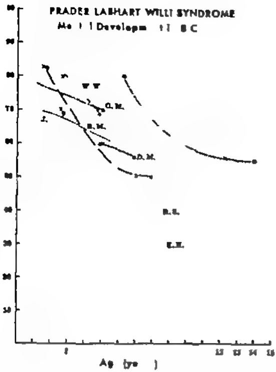

Fig 25 Prader–Labhart Willi syndrome. Mental development in 8 cases.

3 infants, whereas they were present, though diminished, in 3 others. After the first year the tendon reflexes could usually be elicited, but they tended to remain sluggish (+1) at least until the second decade. Simultaneously muscle tone improved but mild hypotonia usually remained, with some laxity of joints and pes planus.

Seven out of 9 children had either a definite squint or at least overaction of an inferior oblique muscle In addition there was a wide variety of minor congenital stigmata, particularly poor modelling of pinnae (Fig. 12) short toenails, and arched palate. Two of our patients had narrow external ear canals as in Down s syndrome, and bilateral simian creases, clinodactyly Brushfield spots on the irides, and mongoloid slanting of the palpebral fissures were also noted in 2 cases each.

Dermatoglyphic pattern

Dermatoglyphic analyses were carried out on all the patients by Dr J R. Miller and are presented in detail in appendix. There were no consistent striking aberrations in the dermal configurations.

The digital patterns were unremarkable with the exception of a relatively rare radial loop on the 3rd digit of the left hand of Case 4 The average total ridge count of 112.8 was low (Canadian population 133 9 $\pm$1 6) Although this appears to be attributable largely to one patient (Case 2), it is of interest that all but one patient (Case 1) were below the average for their sex, and this point regarding ridge count should be clarified in a larger sample.

The palmar patterns appeared to show normal variations. There were no thenar+Int_1 or Int_2 patterns. Loop distal patterns occured in Int_3 and Int_4 with expected frequency With the exception of one patient (Case 5) who had a A /W^t/A pattern, the hypothenar patterns were unremarkable Only one patient (Case 2) had a significant displacement of the axial triradius (*atd* angle 59 *ht* 33.3%)

On the hallucal area the patterns were distal loops or whorls. There were no obvious aberrations in plantar patterns.

Development

The growth charts of Cases 1 to 5 demonstrate that the weight tended to be *below* the 16th per centile for at least the first year when the infant often presented feeding problems during the amyotonic phase. In the second or third year the weight rose, and abnormal fat deposition on trunk and buttocks was often evident. If we exclude Case 9 whose food intake may have been severely restricted, we see from Table 1 that the weight rose above the normal range (i.e. above +2 SD for the height-age) at ages varying from 2 to 6 years, with a mean of 3 years $1^1/_2$ months. In contrast, the stature sometimes tended to drop more below the mean *after* the first year (Cases 1 2, 5), and growth did not accelerate notably with weight gain.

Table 1 also shows the delay in the passage of developmental milestones. The patients remained sitting freely at 10 months to $1^1/_2$ years, with a mean of 13 months, and they learned to walk freely at 18 to 39 months, with a mean of 25 months. They were reported to have said the first word with meaning at 10 to 24 months, with a mean of 16 months. Despite the delay in the acquisition of locomotor and language skills these children were usually alert and responsive, particularly in their second and third years, and adaptive and personal-social abilities were relatively good As in Down s syndrome the early developmental and even intellectual assessments often gave more hopeful results than later psychometric

tests. Fig. 25 demonstrates this relative downward trend in the D.Q. and I.Q. scores of 8 patients during the pre-school years. Thus the I.Q. level depends upon the age. In our 5 patients above the age of 8 years the latest global I.Q. assessment ranged from about 30 to 56 (Table 1).

INVESTIGATIONS

Radiological studies

X-ray examination of an arm was performed in all 9 patients (see Table 3). In 6 the bones and muscle bulk were both considered normal, but in 3 the long bones appeared slender and poorly mineralized, and in 2 of these the muscle masses were considered abnormally small. After infancy extensive soft fatty shadows were often evident. The *bone age* at the hand and wrist (22) was significantly retarded in all the 6 boys who were x-rayed before the age of 4 years, but not in the one girl (Case 4). In two boys (Cases 3 and 5) the delay in the bone age was no longer significant (i.e. less than −2 SD) at 4 years 8 months and 5 years 8 months, respectively, whereas in 2 others it was still significant at 8 and 9 / years, respectively, though to a lessened extent. In the adult male (Case 6) the elbow and knee showed mature bone development at 20 years. The older of the two girls also had a normal bone age at the wrist, hand, elbow and knee at 13 /$_2$ years.

Skull films were obtained in 6 of these children and were generally unremarkable apart from minor abnormalities of the vault in Cases 1 and 2. In the former, at 2 years 4 months, the anterior fontanelle was still open and the posterior fossa somewhat wide. In the latter, at 1 year 9 months, the anterior fossa appeared somewhat narrow with unusually steep slope of its floor.

A pneumoencephalogram was only performed in one of our patients (Case 8) and proved normal apart from moderate dilatation of the 3rd and lateral ventricles. It was not considered justifiable to carry out this investigation in the other patients.

Electroencephalograms

These were recorded in 5 of our patients on one or more occasions. Each had at least one normal record, but Case 9 (who may have some superimposed brain damage from perinatal anoxia) had basynchronous spike discharges at 4 /$_2$ years, mainly in the occipital leads, and Case 8 had low voltage irregular fast activity in all head regions as well as some alpha rhythm at 13 $^1/_2$ years.

Electromyograms, nerve conduction studies and muscle biopsies

The electromyogram in 4 and motor nerve conduction studies in 6 of our patients gave normal results for the age. Muscle biopsies were normal in 2 children, and in the third (Case 1) showed only somewhat small muscle fibers. In one of the children with a normal biopsy (Case 5) the motor end plates in the deltoid muscle were well impregnated with intravital methylene blue and were also shown to be normal. The lateral rectus muscle of the eye contained some fibrous tissue in Case 3.

Blood counts. Serology

Blood counts were normal in all patients except Case 9 who had a mild anemia, presumably due to iron deficiency. The VDRL serum precipitation or Kahn tests were uniformly negative.

Biochemical studies

Serum electrolyte and blood urea nitrogen levels and routine urinalyses were within normal limits in these patients. The serum cholesterol concentration was examined in 5 cases, and as shown in Table 3 the results were also essentially normal. The urinary amino-acids were checked by paper chromatography in 7 patients and were normal in pattern and quantity. The serum protein-bound iodine (PBI) concentration was slightly low (3.4 and 3.8 µg, respectively) in 2 children (Cases 1 and 4) during the second year, but there was no clinical evidence of hypothyroidism. In 6 other patients the level of serum PBI was normal.

The urinary excretion of 17-ketosteroids was examined in 6 cases, and the results were within normal limits, though the values of 2.0 mg per 24 hours at 3 years 8 months and 3.32 mg per 24 hours at 4 /$_2$ years in Cases 1 and 3, respectively, are both somewhat high. The urinary excretion of 17-ketogenic steroids was examined in 4 children and was unusually high at 9.2 and 6.81 mg per 24 hours, respectively, in the same two boys (see 41).

The effect of metyrapone (40 and 50 mg per kg body weight, respectively, in 6 divided doses over 24 hours) on the urinary excretion of

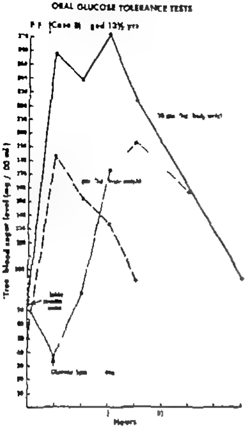

Fig 26 Case 8 P F aged 13 / years. Oral glucose tolerance test.

17 ketogenic steroids was checked in 2 boys, and both exhibited a normal rise to more than twice the original amount (Table 3)

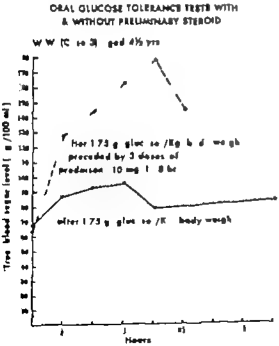

Fig 27 Case 3 W W aged 4 / years. Oral glucose tolerance tests with and without preliminary steroid.

The fasting blood sugar levels of our patients were normal except in R. S. (Case 6) who had levels of 94 110 and 108 mg/100 ml at 20 years. Oral *glucose tolerance tests* were performed in 8 cases, using 1 75 g of glucose per kg body weight up to a maximum of 100 g, and examining skinprick blood by a modified Somogyi Nelson technique *Five out of 8 patients had at least one* high curve, rising above 160 mg/100 ml at 1 hour *or* above 120 mg/100 ml at 2 hours. However since obese children in general often have some impairment of glucose tolerance (67) and the test is influenced by many factors (e g. rate of gastric emptying, previous intake of carbohydrates presence of even mild infections) we thought it best to apply the criteria of Fajans and Conn (*17*) i.e. we considered a curve as diabetic only if the blood sugar level was at or above 160 mg/100 ml after 1 hour 140 *mg* at $1^1/_2$ hours *and* 120 mg after 2 hours By this standard only one patient the girl of $13^1/_2$ years (Case 8), had an abnormal curve (Fig. 26) and this was confirmed in the insulin glucose tolerance test using only 1 g of glucose per kg body weight, so that she is evidently a subclinical diabetic. After priming with cortisone (17) hydrocortisone or prednisone, the glucose tolerance test was repeated in 7 patients. In 3 of these the blood sugar curve rose notably higher than without steroid stress, and in 1 of them (Case 3) it demonstrated a prediabetic state, with a 2 hour blood sugar level of 179 mg/100 ml (Fig. 27) In the two other boys (Cases 7 and 9) the test failed to attain the critical blood glucose level of 140 mg/100 ml at 2 hours.

Insulin sensitivity tests were performed in 2 patients (Cases 6 and 9), 0 1 unit being given i.v per kg *body weight*, and the resulting fall and subsequent rise in the blood sugar level were normal in both.

The fasting *plasma insulin level* was examined in 7 of our cases by Dr J M Martin, of the Hospital for Sick Children in Toronto using the double antibody technique (46). All the values were in the normal range *of 0–20 μU/ml* The plasma insulin values were then determined serially *after* an oral glucose load of 1 g per kg body weight in 5 patients, including the two diabetes suspects (Cases 8 and 3) (Table 4) The $14^1/_2$-year-old girl (Case 8) appeared to have decidedly raised values at 1 to 2 hours, as compared to normal *controls. Three other cases (1*

3 and 4) also had somewhat high levels but these were not so impressive.

Dr J. M. Martin also examined the plasma of 6 of our patients for the presence of the *synalbumin insulin antagonist* described by Vallance-Owen (66,63). The method has been reported previously (15) and reduction of standard insulin activity by more than 50% is usually considered indicative of antagonistic effect, while −40 to −50% is borderline. Only 1 of the 6 children with PLW syndrome (Case 5) showed a significant amount of insulin antagonism (Table 5). We then examined the rest of his family for synalbumin antagonist (Table 6) and found it definitely present in his brother S. and possibly in C. The values of −35.5% in the brother K. and the mother are not strictly significant, but as the trait is evidently dominant (64, 15) one might suspect its presence at least in the mother. On the other hand, there is no history of diabetes in the family at all.

Growth hormone

The plasma levels of growth hormone in 5 patients were determined by Dr J. M. Martin according to the double antibody method described by Morgan (45). The results are listed in Table 7 and are within the normal range.

Gonadotrophin

The urinary FSH excretion was only measured in two cases. In the adolescent patient (Case 6) it was low normal (6–16 mouse uterine units per 24 hours), and in the infant aged 1 year it was already 8 mouse units per 24 hours.

Spinal fluid

The spinal fluid was examined in 2 cases (Case 1 and 3) and proved entirely normal in pressure and composition (cells, protein and sugar content).

Buccal smear

In 5 boys the buccal smear was chromatin-negative One girl (Case 8) had chromatin-positive cells.

Chromosomes

These were examined in 6 boys and in both girls. Case 1 has an XYY karyotype, and it is noteworthy that this does not appear to have caused any special features in his phenotype which would differentiate him from other cases of the PLW syndrome Two boys (Cases 3 and 9) have a "long Y" of about the same length as chromosomes in the group 16–18 and the father of Case 3 was shown to have a similar Y The father of Case 9 was not examined. Case 3 also exhibited a prominent secondary constriction on the long arm of one of the chromosomes in group 6–12+X in 19 out of 82 cells. The remaining 5 patients had a normal karyotype appropriate to their sex.

Blood groups

The blood of eight of these patients and some members of their families was typed by the Rh Laboratory Winnipeg. The results are shown in the Appendix. So far they have not helped our understanding of the inheritance of the disease but they are recorded here so that they can be added to the studies of other cases in future and thereby facilitate the analysis of larger samples.

DISCUSSION

It will be apparent from these case reports that there is indeed a grouping of *clinical features* amounting to a distinct syndrome as described by Prader and his colleagues. A particular notable feature is the initial hypotonia and weakness, which may have been evident to the mother in poor fetal movements even before birth and which is associated with feeding difficulties during the first year Accordingly the weight gain is usually *below* average in the first year and does not become excessive until the second year This gives the weight curve a characteristic "biphasic" appearance well shown in Figs. 3 6, 13 and 18 Prader and Willi (49) mentioned that the typical obesity develops gradually at about 2 years Evans (16) noted that the weight did not rise above the normal range until a mean age of $2^1/_2$ years, and in our experience the weight only exceeded 2 SD above the mean for the height-age at an average of 3 years $1^1/_2$ months. In contrast to the height of obese children in general, the stature tended to remain below the average for the age, though only 3 of the 9 patients were significantly small Along with the somewhat subnormal growth there was frequently delay in dentition, in closure of the anterior fontanelle and in epiphyseal maturation. Behavioral development was also delayed this delay was particularly marked in the locomotor sphere initially as one might expect with the associated weakness and hypotonia. In general, it seems a valid approximation to say that these children "sit at 1 and walk at 2 years" (49) (see Table 1) However apart from locomotion, the delay also involved language development, and after th first 2–3 years the general mental retardation became increasingly evident (Fig. 25) On physical examination the children showed not only acromicria but also a somewhat characteristic facies with pleasant features, and a variety of minor congenital stigmata (Table 2). Among these we have emphasized the frequent enamel defect and dental caries, and the squints (13 29). The boys also exhibited hypogenitalism which pointed to the

diagnosis in all the 7 males in our series the testes were impalpable and the scrotum was small. The occurrence of diabetes mellitus is inconstant and is usually delayed until the teen years, but may sometimes be predicted by a gradual reduction of glucose tolerance, especially on priming with steroids.

The radiological "*bone age*" at the hand and wrist (22) was significantly low in all the 6 boys who were examined before the age of 4 years but not in the one girl (Case 4). After that age epiphyseal maturation may "catch up" although the delay was still significant (over −2 SD) at nearly 8 and 9 / years in Cases 1 and 9 respectively. This delay in bone age was also noted by Prader *et al.* (48), Evans (16) and Dubowitz (10). Retarded bone age was not found in the 4 cases recorded by Hooft and his colleagues (29), and it may be relevant that 3 of these were girls.

Skull x-rays have generally shown little abnormality apart from minor deformities of the vault. *Pneumoencephalograms* have been performed in several published cases and have usually either been normal (49, 4, 16, 29), or shown moderate ventricular dilatation as in our Case 9 (18, 29). Slight cortical atrophy was suspected in one patient (16). The spinal fluid has generally been normal in pressure and in cell, protein and sugar content, and presumably any ventricular dilatation is secondary to cerebral maldevelopment or atrophy.

The *electroencephalogram* is commonly within normal limits for the age (49, 4, 16, 29), and our 5 patients, in whom the EEG was checked, had at least one normal record each. However immature patterns for the age may be encountered (18) as in other retarded children, and some dysrhythmias have been observed as in our Cases 8 and 9. Thus symmetrical slow waves at 3 cycles per second were noted in one of Royer's (55) patients and bilateral theta rhythms were dominant in the case described by Sánchez Villares *et al.* (56), while one of Hooft's (29) patients had sharp and slow waves posteriorly. One may speculate whether such dysrhythmias could be secondary to anoxic cerebral insults, particularly in the perinatal period. Zellweger and his co-authors (7*) commented on the frequent absence of sleep spindles. Gross epileptiform patterns and clinical seizures are evidently uncommon (cf. Evans (16) Case 7).

The *electromyogram* was normal in 4 of our patients. It was also normal in 3 of Evans (16), 3 of Hooft's (29) and 5 of Laurance's (39) cases. In Hooft's remaining patient (No. 3) and in that of Sánchez Villares (56) evidence of denervation was said to have been found. *Motor nerve conduction studies* were carried out in 6 of our children, particularly in median nerves, and the results were always within normal limits (cf. 20, 11). Nerve conduction was also normal in a few other recorded cases (18, 29). *Muscle biopsies* in 3 of our patients were essentially normal, although Case 1 appeared to have somewhat small muscle fibers, as has been reported in some cases of benign congenital hypotonia (21). In previously recorded patients the muscle biopsy has usually proved normal. Only in one case it is said to have shown neurogenic atrophy (56). In one other intravital staining demonstrated some finely beaded fibers in the smaller nerve bundles (39). Our own findings suggest that there is usually no evidence of any lower motor neurone or muscle disease in these children despite the marked hypotonia and depressed tendon reflexes in infancy.

Endocrine disturbances

In view of the small stature and retarded bone age *thyroid function* has often been investigated. In general, the serum protein-bound iodine (PBI) level has been found to be normal (16, 29). In a 17 year-old patient with borderline low serum PBI and low radioactive iodine uptake, thyroid function responded well to the administration of thyrotropic hormone; this suggested pituitary dysfunction rather than primary hypothyroidism. Similarly although two of our patients exhibited slightly low levels of serum PBI (3.4 and 3.8 μg/100 ml) in their second year they presented no clinical signs of hypothyroidism and subsequently maintained a normal serum PBI concentration after a course of thyroid therapy. Six other patients had PBI levels within the normal range.

In regard to *adrenocortical function* it must be kept in mind that obese children generally tend to exhibit some overactivity of the adrenal cortex (see 69). Accordingly Cohen (6) found the urinary excretion of 17 ketogenic steroids to be

* Personal communication by J. Landwirth, A. H. Schwartz and I. A. Grant (74).

DISCUSSION

It will be apparent from these case reports that there is indeed a grouping of *clinical features* amounting to a distinct syndrome as described by Prader and his colleagues. A particular notable feature is the initial hypotonia and weakness, which may have been evident to the mother in poor fetal movements even before birth and which is associated with feeding difficulties during the first year Accordingly the weight gain is usually *below* average in the first year and does not become excessive until the second year This gives the weight curve a characteristic biphasic appearance well shown in Figs. 3 6 13 and 18. Prader and Willi (49) mentioned that the typical obesity develops gradually at about 2 years Evans (16) noted that the weight did not rise above the normal range until a mean age of $2^1/_2$ years, and in our experience the weight only exceeded 2 SD above the mean for the height-age at an average of 3 years $1^1/_2$ months. In contrast to the height of obese children in general the stature tended to remain below the average for the age, though only 3 of the 9 patients were significantly small Along with the somewhat subnormal growth there was frequently delay in dentition, in closure of the anterior fontanelle and in epiphyseal maturation Behavioral development was also delayed this delay was particularly marked in the locomotor sphere initially as one might expect with the associated weakness and hypotonia. In general it seems a valid approximation to say that these children "sit at 1 and walk at 2 years" (49) (see Table 1) However apart from locomotion, the delay also involved language development, and after the first 2–3 years the general mental retardation became increasingly evident (Fig. 25) On physical examination the children showed not only acromicria but also a somewhat characteristic facies with pleasant features, and a variety of minor congenital stigmata (Table 2) Among these we have emphasized the frequent enamel defect and dental caries, and the squints (13 29). The boys also exhibited hypogenitalism which pointed to the

early stages of diabetes mellitus. Karam and his colleagues (32) claim that excessive serum insulin responses to a glucose load are more closely correlated with obesity *per se* than with the diabetic state, and Grodsky *et al.* (23) consider that such responses may be of limited value as a sign of prediabetes. On the other hand, Yalow *et al.* (70) find that plasma insulin responses to glucose are somewhat higher than normal in obesity without diabetes but much greater than normal in mild or moderate untreated diabetes of the maturity onset type. We thought it worthwhile to investigate this in our patients, but the results are equivocal. After an oral glucose load in 5 cases the plasma insulin level appeared to rise abnormally in the subclinically diabetic girl, but only to borderline high values in 3 others as compared to 6 controls (Table 4).

A search for excessive synalbumin antagonism to insulin was also considered indicated, since it has been claimed that this can be regarded as a biochemical marker of "essential diabetics" (64). However although Vallance-Owen's (63) preliminary observations indicate that 20 to 25% of the population may be so constituted, Dr. J. M. Martin found significant synalbumin antagonism in only one of 6 patients in our series (Table 5). At least one of this boy's brothers also exhibited such insulin antagonism (Table 6) but it is interesting that there is no history of diabetes in his family.

In future investigations of the pre-diabetic state it may be rewarding to measure the degradation rate of insulin (60) and the blood levels of non-esterified fatty acid (NEFA). According to the hypothesis proposed by Randle and his colleagues (51), the fasting plasma concentration of NEFA may be increased in diabetes mellitus of the maturity-onset type despite elevated concentrations of glucose and high levels of insulin. After an oral glucose load the plasma concentration of NEFA may then only fall slowly and may impair glucose tolerance and insulin sensitivity. The serum levels of lipids and lipoproteins may also be relevant and have been measured in some cases of the PLW syndrome (4, 29, 39). On the other hand, some recent studies suggest that tests directly concerned with glucose metabolism, and particularly the cortisone-glucose tolerance test, are still most likely to prove useful in demonstrating the pre-diabetic state (53).

It is tempting to suspect a *hypothalamic defect* in this syndrome, since such a defect might explain not only the small stature, hypogenitalism and delayed puberty (in males), but also the obesity and even the tendency to diabetes mellitus. Bilateral lesions in or along the lateral border of the ventromedial nuclei of the hypothalamus in rats cause hyperphagia and obesity (27), and electrical stimulation of the lateral part of the hypothalamus in cats and goats also increases food intake (37). Hence a ventromedial "satiety center" and a lateral "feeding center" have been postulated. Ablation of the ventromedial nuclei also reduces spontaneous activity and thereby contributes to weight gain. In animals selective permeability or transport of glucose and tracer substances into this "satiety center" has been demonstrated (37, 43). Thus a defect of satiety could be due to a structural or functional abnormality in this region. To explain the aphagia and anorexia during early infancy in the PLW syndrome Evans (16) has further suggested that the lateral centers in the hypothalamus may mature late in these patients.

It has also been proposed that the "satiety center" acts primarily by exerting "lipostatic" control, i.e. by stabilizing the body's fat stores. The nature of the messenger substance which normally influences the activity of the area is uncertain, but it might be insulin (34). Hales and Kennedy (24) showed that hyperphagic rats which had lesions in the ventromedial nuclei and unlimited access to food for 3 months, had significantly higher plasma concentration of NEFA and insulin after feeding than untreated control animals, and the plasma levels of both substances remained increased after starvation for 24 hours. These abnormalities resemble those in human obesity and in diabetes mellitus of the maturity-onset type. Since a high plasma level of NEFA causes insulin resistance, the consequent increase in the secretion of insulin could eventually lead to functional insufficiency of pancreatic β-cells and thus to the diabetic state. In any case, it has been shown in monkeys and rodents that bilateral electrolytic lesions of the ventromedial nuclei of the hypothalamus cause not only hyperphagia and obesity, but will also lead to diabetes mellitus in a proportion of the animals (25, 26).

Gonadal atrophy and interruption of growth have also been produced by hypothalamic lesions

elevated in such children, while the excretion of 17 ketosteroids was usually at the upper limit of the normal range or only slightly raised. This appeared to be an effect of overnutrition, since weight reduction was invariably associated with a fall in the excretion of both types of steroid. Our own results are in accord with these findings. The urinary excretion of 17 ketogenic steroids appeared unusually high and that of 17-ketosteroids also somewhat high in two boys (Case 1 and 3) who were obese and gaining weight rapidly at 3 years 8 months and 4½ years, respectively (see 41) The excretion of 17 ketogenic steroids was normal in Case 1 at an earlier age and also in two other patients. The excretion of 17 ketosteroids was also normal earlier in Case 1 and at various ages in 4 other patients (see Table 3) In Laurance s (39) cases adrenocortical function also appeared normal when assessed by serum electrolyte levels, water load tests, steroid excretion and response to ACTH.

In this connection, two points should be noted. First, Prader and his colleagues (47) found the excretion of 17 ketosteroids in the older patients strikingly reduced, and in the 43-year-old male described by Juul and Dupont (31) it was at the lower limit of the normal range (9 8 mg per 24 hours). The latter patient also had a low level of plasma testosterone and of urinary androsterone. The reduced production of 17 ketosteroids is probably due to *hypofunction of the testes* rather than the adrenals, for it is also known that the urinary excretion of gonadotrophin and FSH in the syndrome may be raised after puberty (49 31) The question then arises whether the cryptorchidism may at times be associated with marked dysgenesis or atrophy of the testes. Testicular biopsies have only been described in 4 patients and have not shown any gross dysgenesis of tubules but the appearances usually encountered in infantile or abdominal testes and variable reduction in the number of Leydig cells (72, 4 39) Testicular function may vary in different cases. In one of Evans (16) patients, aged 16 years, and in our case 6, at 20 years, the urinary excretion of 17 ketosteroids and of FSH were within normal limits. In general, the presence of the prostate gland and of puberty changes (albeit often delayed and incomplete) indicate at least partial testicular functioning, and thus is also suggested by the increased excretion of androsterone after injection of human chorionic gonadotrophin (44)

Secondly the *pituitary-adrenal relationships* have been investigated with divergent results. Bühler *et al* (4) Forssman and Hagberg (18) and Sugarman and Boder (61) noted that the levels of urinary 17-hydroxycorticosteroids in their respective patients did not rise satisfactorily after administration of either corticotrophin or metyrapone. Other authors have found a normal response to corticotrophin (16 29 39) and in our Cases 3 and 9 as well as in 6 other patients in the literature the metyrapone test gave normal results (36 44 29 39). In connection with the latter test, Laurian and his colleagues (40) have recently pointed out that obese children frequently show a poor response to metyrapone, and particularly boys with "gynoid type of obesity"

In future, assays of corticotrophin and of thyroid-stimulating hormone will be of interest in the assessment of *pituitary function* in the PLW syndrome. The levels of growth hormone were normal in 5 of our patients (Table 7) and in one previous case (4) The urinary excretion of gonadotrophin before puberty was low (54 28) or normal (36 39) and subsequently as mentioned, it tended to be normal or raised. To date the clinical and laboratory findings are more in keeping with those found in delayed puberty than in pituitary infantilism (see 9)

The high incidence of the maturity-onset type of *diabetes mellitus* in the syndrome is unusual in pediatric experience and makes the children suitable subjects for a study of the pre-diabetic and subclinical diabetic state. Evans (16) noted that out of 7 patients, 4 had impaired glucose tolerance tests and 2 with normal results had deficient glucose tolerance after cortisone. Royer (55) described the evolution of diabetes in one patient. Applying the strict criteria of Fajans and Conn (17) we found that out of 8 patients, 1 was diabetic (Case 8). Another appeared to have prediabetes on the basis of the prednisone-glucose tolerance test. Five of the others had a somewhat high blood sugar curve on at least one occasion or without steroid priming, but failed to reach significantly high levels at the appropriate time It is, of course, quite possible that some of these may still develop more evidence of diabetes later

There is some divergence of opinion concerning the significance of plasma insulin levels in the

early stages of diabetes mellitus. Karam and his colleagues (32) claim that excessive serum insulin responses to a glucose load are more closely correlated with obesity *per se* than with the diabetic state, and Grodsky *et al.* (23) consider that such responses may be of limited value as a sign of pre diabetes. On the other hand, Yalow *et al* (70) find that plasma insulin responses to glucose are somewhat higher than normal in obesity without diabetes but much greater than normal in mild or moderate untreated diabetes of the maturity onset type. We thought it worthwhile to investigate this in our patients, but the results are equivocal. After an oral glucose load in 5 cases the plasma insulin level appeared to rise abnormally in the subclinically diabetic girl, but only to borderline high values in 3 others as compared to 6 controls (Table 4).

A search for excessive synalbumin antagonism to insulin was also considered indicated, since it has been claimed that this can be regarded as a biochemical marker of essential diabetics (64). However although Vallance-Owen's (63) preliminary observations indicate that 20 to 25% of the population may be so constituted, Dr J M Martin found significant synalbumin antagonism in only one of 6 patients in our series (Table 5). At least one of this boy's brothers also exhibited such insulin antagonism (Table 6) but it is interesting that there is no history of diabetes in his family

In future investigations of the pre-diabetic state it may be rewarding to measure the degradation rate of insulin (60) and the blood levels of non-esterified fatty acid (NEFA) According to the hypothesis proposed by Randle and his colleagues (51), the fasting plasma concentration of NEFA may be increased in diabetes mellitus of the maturity-onset type despite elevated concentrations of glucose and high levels of insulin After an oral glucose load the plasma concentration of NEFA may then only fall slowly and may impair glucose tolerance and insulin sensitivity The serum levels of lipids and lipoproteins may also be relevant and have been measured in some cases of the PLW syndrome (4 29 39). On the other hand, some recent studies suggest that tests directly concerned with glucose metabolism, and particularly the cortisone-glucose tolerance test, are still most likely to prove useful in demonstrating the pre-diabetic state (53).

It is tempting to suspect a *hypothalamic d fect* in this syndrome, since such a defect might explain not only the small stature, hypogenitalism and delayed puberty (in males), but also the obesity and even the tendency to diabetes mellitus. Bilateral lesions in or along the lateral border of the ventromedial nuclei of the hypothalamus in rats cause hyperphagia and obesity (27), and electrical stimulation of the lateral part of the hypothalamus in cats and goats also increases food intake (37) Hence a ventromedial "satiety center" and a lateral "feeding center" have been postulated. Ablation of the ventromedial nuclei also reduces spontaneous activity and thereby contributes to weight gain. In animals selective permeability or transport of glucose and tracer substances into this "satiety center" has been demonstrated (37 43). Thus a defect of satiety could be due to a structural or functional abnormality in this region. To explain the aphagia and anorexia during early infancy in the PLW syndrome Evans (16) has further suggested that the lateral centers in the hypothalamus may mature late in these patients.

It has also been proposed that the "satiety center" acts primarily by exerting "lipostatic" control, i e by stabilizing the body's fat stores. The nature of the messenger substance which normally influences the activity of the area is uncertain, but it might be insulin (34). Hales and Kennedy (24) showed that hyperphagic rats which had lesions in the ventromedial nuclei and unlimited access to food for 3 months, had significantly higher plasma concentration of NEFA and insulin after feeding than untreated control animals, and the plasma levels of both substances remained increased after starvation for 24 hours. These abnormalities resemble those in human obesity and in diabetes mellitus of the maturity-onset type. Since a high plasma level of NEFA causes insulin resistance, the consequent increase in the secretion of insulin could eventually lead to functional insufficiency of pancreatic β-cells and thus to the diabetic state. In any case, it has been shown in monkeys and rodents that bilateral electrolytic lesions of the ventromedial nuclei of the hypothalamus cause not only hyperphagia and obesity but will also lead to diabetes mellitus in a proportion of the animals (25 26).

Gonadal atrophy and interruption of growth have also been produced by hypothalamic lesions

in rats, but the responsive region of the hypothalamus was more diffuse than that concerned in the regulation of appetite and extended through much of the medial and posterior parts (33) Another feature in the PLW syndrome which could be explained by a hypothalamic defect is the disturbance in the diurnal variation of plasma 11 hydroxycorticosteroid levels observed in 2 out of 3 patients by Monnens and Kenis (44) No doubt there are more extensive cerebral defects in the syndrome to account for the mental deficiency

The *relationship to other presumed hypothalamic syndromes* is still unclear Among inborn defects there is particularly the Laurence-Moon-Biedl syndrome, in which obesity hypogenitalism and mental retardation are also associated with other abnormalities. However the mental retardation is usually only *mild* and the *accompanying* defects (particularly polydactyly and retinitis pigmentosa) are different. Weiss (68) described a variant of that syndrome, in which "cerebral adiposity" mental deficiency and "genital dystrophy" were combined with nerve deafness instead of retinitis pigmentosa. Solis-Cohen and Weiss (59) noted the occasional occurrence of diabetes mellitus with Fröhlich's syndrome (adiposogenital dystrophy) Alström and his colleagues (1) described 3 cases of a new syndrome, in which obesity and atypical retinal degeneration were associated with nerve deafness and diabetes mellitus. There was no mental retardation and no gross hypogenitalism, but testicular biopsy in one case showed some tubular sclerosis. Finally Lynch and his co-workers (42) recently reported a large kindred which included two siblings showing *juvenile* diabetes mellitus, hyperlipemia, hypogonadism and dwarfism. In addition, varying combinations of juvenile and late-onset diabetes mellitus with hyperlipemia and short stature were found in many relatives. However mental deficiency obesity and hypotonia were not observed in that pedigree

Incidentally the PLW syndrome forms an interesting contrast to a possible diencephalic syndrome of lipodystrophy and gigantism with associated endocrine manifestations (58) Patients affected by that syndrome are thought to have a congenital lack of subcutaneous fat and have an emaciated appearance. *They also have an increased* rate of growth with an acromegaloid pattern and *large* hands and feet, and they exhibit generalized muscular hypertrophy In females the labia majora and clitoris are moderately hypertrophic. Disturbances of carbohydrate metabolism may also occur in that condition, and although the intelligence is usually normal it may be subnormal and the pneumoencephalogram may indicate some cerebral atrophy

Genetic aspects

The *chromosomes* of our patients are noteworthy (Table 3). Case 1 is the only recorded instance of the Prader–Labhart–Willi syndrome *with an XYY karyotype Prior to mid-1965 only 11 instances of this particular chromosome abnor*mality had been reported, and there did not appear to be any consistent associated clinical picture (2) Indeed, the first recorded patient with *this karyotype had no genital or gross somatic* anomalies, though he was tall and obese. He was discovered on routine testing, as he was the father of a girl with Down's syndrome and of other abnormal offspring (57) Similarly patients with the XXYY chromosome abnormality showed clinical features of Klinefelter's syndrome very much like those with the XXY karyotype, with the possible exception of greater skeletal maturation and a more abnormal dermatoglyphic pattern in XXYY cases (3 62) It was therefore thought that the Y chromosome bore relatively little genetic information, compared with the autosomes and the X chromosomes, other than that concerned with male sex determination. Our Case 1 supported this concept, since his phenotype is closely similar to that of other patients with the PLW syndrome who have normal chromosomes. In 1965–66 it was *reported that 9 instances of XYY* males were found among 315 patients with aggressive and violent propensities in a mental hospital (30 50). Eight of these were high-grade defectives, and 6 were over 6 ft (183 cm) in height there were no other physical abnormalities. In contrast to this high incidence the XYY abnormality was found only once among 2000 male control chromosome counts (35) *Further among 21 chromatin-positive* patients liable to criminal behavior 7 had the XXYY chromosome abnormality whereas usually less than 1 in 10 chromatin-positive cases have this karyotype (5) It therefore seems that an *extra Y chromosome* predisposes to aggressive antisocial behavior and unusually tall stature So

far our Case 1 has not shown either of these characteristics. However his bone age is still significantly retarded at the age of 8 years, so the epiphyses may yet fuse late and allow continued growth.

The presence of a "long Y" chromosome (with the same length as group 16–18) in 2 of the other 5 boys with a known karyotype in our series also deserves comment, for this anomaly is found in fewer than 3% of randomly chosen males (8). Altogether 3 out of 8 patients with known karyotype in our experience thus have at least a minor chromosome anomaly. Further four instances of anomalies affecting group D or E chromosomes, again with little effect on the phenotype, have been recorded with this syndrome, namely a probable translocation of 2 chromosomes (4) and mosaicism for trisomy of a chromosome (54) within the D group and also a 14–18 translocation (71) and an abnormal chromosome No. 16 (10). This total of 7 patients would seem to represent a somewhat high incidence of minor chromosomal anomalies in the approximately 70 cases of the PLW syndrome known to me, although such instances of the condition with associated chromosome abnormalities are perhaps particularly likely to be reported. One may at least speculate whether minor chromosomal aberrations are unduly common in the Prader–Labhart–Willi as in Down syndrome (see 14).

It is evident that the PLW syndrome involves not only the nervous system, even though a hypothalamic defect may go far to explain the endocrine and metabolic derangement. The acromicria, enamel hypoplasia, peculiar facies and many so-called degenerative stigmata (see Table 2) indicate a more widespread disturbance in fetal development. The variable minor aberrations of dermatoglyphic patterns and of chromosomal karyotype in some cases are also in keeping with this concept. No notable diseases have occurred during gestation in the recorded cases, and it seems likely that the cause of the syndrome is genetic. Its various manifestations might then all be due to pleiotropic gene, as suggested by Prader and Willi (49). As to the mode of inheritance it is tempting to suggest that the condition is due to an autosomal recessive trait like the Alström and Laurence–Moon–Biedl syndromes, which show some similar features. It is, however surprising that Gabilan's (19) somewhat atypical patients include the only recorded siblings with the disease and the only recorded child with consanguineous parents. Until more familial aggregation of the syndrome is demonstrated, it is also possible that the condition may be due to a recurrent autosomal dominant mutation (J. R. Miller personal communication).

Treatment

Lastly in the management of this disease we have found that the obesity is as great a problem to the parents as the mental retardation. We have treated the obesity with activation and low-calorie diets, but the appetite seems truly voracious. Phenmetrazine has appeared slightly more effective than the amphetamines in reducing it. In view of the mental defect the question of hormonal or surgical treatment for cryptorchidism rarely arises. In regard to pre-diabetes and subclinical diabetes we have wondered whether tolbutamide might be administered in order to prevent exhaustion of the pancreatic β-cells, but its value in this respect still seems controversial. It was found successful in the treatment of the frank diabetic state by Royer (55) but not by Larbre *et al.* (36).

SUMMARY

In 1956 Prader and his associates described a syndrome of obesity small stature, acromicria and oligophrenia, regularly preceded by an amyotonic state in the newborn period. The males also had a hypoplastic flat scrotum, inguinal or abdominal retention of testes and delayed puberty. A tendency to the development of diabetes mellitus in the teenage years was also noted, and the diabetes was of the type normally encountered with onset at maturity rather than in childhood.

About 70 cases of this syndrome have been published to date. The literature is reviewed, and details concerning 9 patients of our own are given. Seven of these 9 are males: this predominance may be influenced by the fact that the hypogenitalism in boys facilitates the diagnosis. The mean parental ages at the birth of our patients were abnormally high, but this finding has not been encountered by other observers. Clinically in addition to the features described by Prader and his colleagues, these patients presented a normal or somewhat large head circumference, delay

in rats, but the responsive region of the hypothalamus was more diffuse than that concerned in the regulation of appetite and extended through much of the *medial and posterior parts* (33) Another feature in the PLW syndrome which could be explained by a hypothalamic defect is the disturbance in the diurnal variation of plasma 11-hydroxycorticosteroid levels observed in 2 out of 3 patients by Monnens and Kenis (44) No doubt there are more extensive cerebral defects in the syndrome to account for the mental deficiency

The *relationship to other presumed hypothalamic syndromes* is still unclear Among inborn defects there is particularly the Laurence-Moon-Biedl syndrome, in which obesity hypogenitalism and mental retardation are also associated with other abnormalities. It was found successful in the treatment of the frank diabetic state by Royer (55) but not by Larbre *et al.* (36).

SUMMARY

In 1956 Prader and his associates described a syndrome of obesity small stature, acromicria and oligophrenia, regularly preceded by an amyotonic state in the newborn period. The males also had a hypoplastic flat scrotum, inguinal or abdominal retention of testes and delayed puberty. A tendency to the development of diabetes mellitus in the teenage years was also noted, and the diabetes was of the type normally encountered with onset at maturity rather than in childhood.

About 70 cases of this syndrome have been published to date. The literature is reviewed, and details concerning 9 patients of our own are given. Seven of these 9 are males, this predominance may be influenced by the fact that the hypogenitalism in boys facilitates the diagnosis. The mean parental ages at the birth of our patients were abnormally high, but this finding has not been encountered by other observers. Clinically in addition to the features described by Prader and his colleagues, these patients presented a normal or somewhat large head circumference delay

in dentition and closure of the anterior fontanelle, marked dental caries often superimposed on defective enamel a somewhat characteristic facies with fair or auburn hair and blue eyes, phimosis in boys, and strabismus. The dermatoglyphic pattern showed no consistent striking aberration but a low average total digital ridge count. The weight tended to be at least 1 SD below the mean during the first year and only became significantly high (above +2 SD for height-age) at a mean age of over 3 years, while growth did not accelerate Behavioral development appeared to slow down during the pre-school years, whereas the initial hypotonia and weakness improved.

The radiological bone age was retarded significantly in boys below the age of 4 years, but not in the one girl who was x-rayed at that time. Electroencephalograms did not show any gross paroxysmal activity but at times revealed dysrhythmic patterns Electrodiagnostic studies and muscle biopsies did not indicate any abnormality of the lower motor neurone or muscles. Glucose tolerance tests in 8 patients showed a diabetic curve in one girl of $13^1/_2$ years and somewhat (but not significantly) high curves in 4 other children. On priming with steroid a boy of $4^1/_2$ years also gave a diabetic response. The fasting plasma levels of insulin in 7 cases were essentially normal the levels after a glucose load appeared to rise abnormally high in the subclinically diabetic girl Synalbumin insulin antagonist was found in only 1 out of 6 patients It was also demonstrated in at least one healthy brother of that boy Plasma growth hormone levels were normal in 5 children. The first case had an XYY chromosome abnormality and two of seven others had minor chromosomal aberrations.

A variety of other biochemical investigations and detailed blood grouping were performed. The findings are discussed, and the possibility of a congenital structural or functional defect of the hypothalamus as an important component of the syndrome is considered The mode of inheritance is not yet clear

ACKNOWLEDGEMENTS

I wish to express my thanks to the various physicians who referred these patients and particularly to Dr E. E. Cook and Dr J U Crichton who arranged for me to see children they had diagnosed in consultation. I am also grateful to Dr J S. Bland, Medical Superintendent, and Dr H Tischler Director of Medical and Paediatric Services, The Woodlands School, New Westminster B C, for permission to include the findings in Cases 6 and 9 which were obtained at the School. I am indebted to Dr J R. Miller for the studies of dermatoglyphs, buccal smears and chromosomes, to Dr J M. Martin for contributing the investigations of plasma insulin levels, growth hormone and synalbumin antagonist, to Dr Bruce Chown, Miss Marion Lewis and Mrs. Hiroko Kata for the blood grouping, to Drs. S. Israels, J U Crichton and J A. Birkbeck for advice and criticism, and to the Department of Medical Illustration, University of British Columbia, for help with the illustrations. Professor C. Hooft, Dr P R. Evans, Dr B. Laurance and Dr D. Hoefnagel kindly gave me information concerning their patients. The Vancouver Foundation defrayed the cost of printing this Supplement.

in dentition and closure of the anterior fontanelle, marked dental caries often superimposed on defective enamel, a somewhat characteristic facies with fair or auburn hair and blue eyes, phimosis in boys, and strabismus. The dermatoglyphic pattern showed no consistent striking aberration but a low average total digital ridge count. The weight tended to be at least 1 SD below the mean during the first year and only became significantly high (above +2 SD for height-age) at a mean age of over 3 years, while growth did not accelerate. Behavioral development appeared to slow down during the pre-school years, whereas the initial hypotonia and weakness improved.

The radiological bone age was retarded significantly in boys below the age of 4 years, but not in the one girl who was x rayed at that time. Electroencephalograms did not show any gross paroxysmal activity but at times revealed dysrhythmic patterns. Electrodiagnostic studies and muscle biopsies did not indicate any abnormality of the lower motor neurone or muscles. Glucose tolerance tests in 8 patients showed a diabetic curve in one girl of $13^1/_2$ years and somewhat (but not significantly) high curves in 4 other children. On priming with steroid a boy of $4^1/_2$ years also gave a diabetic response. The fasting plasma levels of insulin in 7 cases were essentially normal the levels after a glucose load appeared to rise abnormally high in the subclinically diabetic girl Synalbumin insulin antagonist was found in only 1 out of 6 patients it was also demonstrated in at least one healthy brother of that boy Plasma growth hormone levels were normal in 5 children. The first case had an XYY chromosome abnormality and two of seven others had minor chromosomal aberrations.

A variety of other biochemical investigations and detailed blood grouping were performed. The findings are discussed, and the possibility of a congenital structural or functional defect of the hypothalamus as an important component of the syndrome is considered. The mode of inheritance is not yet clear

ACKNOWLEDGEMENTS

I wish to express my thanks to the various physicians who referred these patients and particularly to Dr E. G. Cook and Dr J U Crichton who arranged for me to see children they had diagnosed in consultation. I am also grateful to Dr J S Bland, Medical Superintendent, and Dr B. Tischler Director of Medical and Paediatric Services, The Woodlands School, New Westminster B.C., for permission to include the findings in Cases 6 and 9 which were obtained at the School. I am indebted to Dr J R. Miller for the studies of dermatoglyphs, buccal smears and chromosomes, to Dr J M. Martin for contributing the investigations of plasma insulin levels, growth hormone and synalbumin antagonist, to Dr Bruce Chown, Miss Marion Lewis and Mrs. Hiroko Kaita for the blood grouping, to Drs. S. Israels, J U Crichton and J A. Birkbeck for advice and criticism, and to the Department of Medical Illustration, University of British Columbia, for help with the illustrations. Professor C. Hooft, Dr P R. Evans, Dr B. Laurance and Dr D. Hoefnagel kindly gave me information concerning their patients. The Vancouver Foundation defrayed the cost of printing this Supplement.

Acknowledgements

My sincere thanks are due to

Professor *Gregers Thomsen* for his keen interest and invaluable criticism at every stage of the work and for excellent working conditions.

Associate Professor *Henning Andersen* who aroused my interest in the subject. Without the benefit of his active support, encouragement and enthusiasm this work would not have been possible.

Professor *J. M. Tanner* and his co-workers for stimulating discussion and for permission to use his figures.

Mogens Nyholm Actuary for his meticulous statistical work and patient interest in the study

Dr. *Axel Birring* Copenhagen County Schools, who enabled me to carry out the examination of school children and Nurse *Ruth Petersen* for technical assistance.

These studies were aided by grants from "Kobmand i Odense Johann og Hanne Weiman, fodt Seedorffs legat" "Thomas Bartholins legat" and Copenhagen County Schools.

Introduction

The present investigation comprised a cross-sectional study of skeletal maturation of the hand and wrist in a series of Danish school children aged 7–18 years. Skeletal maturity was related to the children's age, stage of puberty and to the environment in which they were raised. The results were also compared with similar results from other countries.

The physical development of children of the same chronological age may vary within wide limits. The biological variation for a given chronological age is least for the younger ages, increasing gradually up to a maximum around puberty and then decreasing slightly.

Fig. 1 illustrates Broman, Dahlberg & Lichtenstein's (1942) curves representing the height of Swedish boys ± 1 and 2½ standard deviations, SD. It is apparent from the curve that chronological age is not a good standard of maturity since a boy of, say 14 years may measure between 139 and 180 cm and yet be of normal height.

Height is also no accurate standard of maturity as a boy of 130 cm may be from 9 to 16 years of age and yet fall within the normal range.

Sometimes a child's development is expressed in terms of its *height age* i.e. the average age at which children of the same sex attain a given height. The height age, when compared with the chronological age, indicates whether the child's growth is retarded or advanced in relation to the average.

Figs. 2 and 3 show Tanner's (1963) diagrams presenting the sequence of the various signs of puberty and the age range within which they appear. Two boys of say 14 years may differ widely in maturity. One may be in full puberty with incipient growth of beard, a deep voice, and fully developed in respect to pubic and axillary hair and genitalia, while the other may be slight and boyish with infantile secondary sex characters.

Because of this great difference in the age at which children enter puberty and because puberty entails such extensive changes in body size, physiology and pattern of behaviour, the mere fact that a boy is 14 years of age does not say much concerning his stage of development. All depends upon whether he is pre-adolescent, mid-adolescent or post-adolescent (Tanner 1963).

Therefore, a search has been made for other ways of assessing the stage of development.

Introduction

The present investigation comprised a cross-sectional study of skeletal maturation of the hand and wrist in a series of Danish school children aged 7–18 years. Skeletal maturity was related to the children's age, stage of puberty and to the environment in which they were raised. The results were also compared with similar results from other countries.

The physical development of children of the same chronological age may vary within wide limits. The biological variation for a given chronological age is least for the younger ages, increasing gradually up to a maximum around puberty and then decreasing slightly.

Fig. 1 illustrates Broman, Dahlberg & Lichtenstein's (1942) curves representing the height of Swedish boys ± 1 and $2^1/_2$ standard deviations, SD. It is apparent from the curve that chronological age is not a good standard of maturity, since a boy of, say 14 years may measure between 139 and 180 cm and yet be of normal height.

Height is also no accurate standard of maturity, as a boy of 150 cm may be from [illegible] to 16 years of age and yet fall within the normal range.

Sometimes a child's development is expressed in terms of its *height age* i.e. the average age at which children of the same sex attain a given height. The height age, when compared with the chronological age, indicates whether the child's growth is retarded or advanced in relation to the average.

Figs. 2 and 3 show Tanner's (1965) diagrams presenting the sequence of the various signs of puberty and the age range within which they appear. Two boys of say 14 years may differ widely in maturity. One may be in full puberty with incipient growth of beard, a deep voice, and fully developed in respect to pubic and axillary hair and genitalia, while the other may be slight and boyish with infantile secondary sex characters.

Because of this great difference in the age at which children enter puberty and because puberty entails such extensive changes in body size, physiology and pattern of behaviour, the mere fact that a boy is 14 years of age does not say much concerning his stage of development. All depends upon whether he is pre-adolescent, mid-adolescent, or post-adolescent (Tanner 1963).

Therefore, a search has been made for other ways of assessing the stage of development.

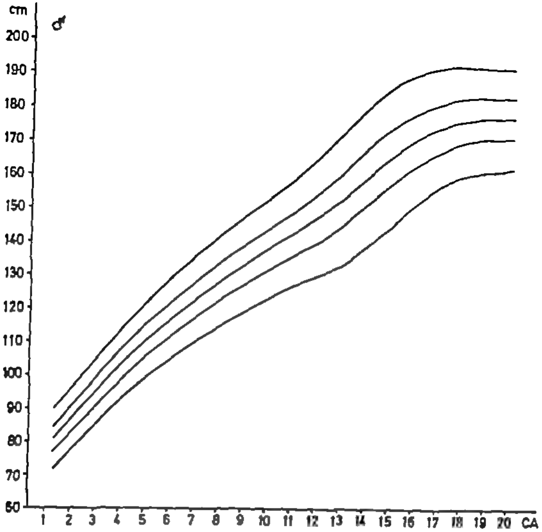

Fig 1

Height of Swedish boys ± 1 and ± 2 /s SD (Broman Dahlberg & Lichtenstein 1942)

Crampton (1908) introduced the concept *physiological age* defined as the number of years which have elapsed since pubescence, i.e. the appearance of pubic hair

In evaluating *biological age* meaning general physical development, criteria such as pubic and axillary hair size of testes, breast development, and menarche have been used During adolescence, i.e. the period of puberal development, these criteria express the stage of development quite well But there was a need for a method by which biological development may be assessed before, during and after puberty

Skeletal maturation has proved to be a graded and fairly accurate standard for assessment of biological age *Skeletal age* expresses the stage of skeletal maturation.

Chapter I

Skeletal Maturation and Methods of Assessment

In the 19th century bones and skeletal maturation were studied by dissecting cadavers. After the detection of X rays in 1895 it was possible to study skeletal maturation in living persons, so that minute differences could be demonstrated by longitudinal investigations.

Formation and Maturation of Long Bones

In a newborn infant a long bone consists of an osseous shaft, the preliminary diaphysis. The bone ends are made of cartilage resembling the final bone. The ossification centres of the bone ends, i.e. secondary centres or epiphyseal centres, usually do not appear until after birth. An exception is the appearance of the epiphyseal centre in the distal part of the femur Beclard's (1820) ossification centre, shortly before birth, in the 9th foetal month. This applies to children of a birth weight ≥ 3000 g (Christie 1949) Frequently the epiphyseal centre in the proximal end of the tibia too is present before birth. The longitudinal growth of the long bones takes place at the diaphyseal ends where they are in contact with the epiphyseal cartilage. Gradually as the epiphysis ossifies, the epiphyseal cartilage is reduced to a narrow disc between the diaphysis and epiphysis. When epiphyseal closure is completed, longitudinal growth must be considered to have ceased.

Maturation of the Hand Skeleton

A number of studies which have contributed to our present knowledge of postnatal skeletal maturation will be reviewed below As the present study concerns the maturation of the hand skeleton, it is natural to concentrate particularly on investigations dealing with the skeletal maturation in the hand and wrist.

The times and the order of appearance of the ossification centres of the carpal bones and epiphyses in the hand have been studied int. al. by Pryor (1907) Todd (1937) Francis & Werle (1939) Robinow (1942) Pyle & Sontag (1943) Stuart & Stevenson (1954) and Garn & Rohmann (1960 a)

The sequence of epiphyseal fusion in the hand has been studied by Todd, Garn, Rohmann & Apfelbaum (1961) Pyle, Stuart, Cornoni & Reed (1961) and Stuart, Pyle, Cornoni & Reed (1962) All these investigations were longitudinal.

Tables 1 and 2 give, for boys and

Object of the Study

As no studies of the skeletal development of Danish children exist their skeletal maturity can be assessed only by foreign systems. A number of earlier and more recent foreign studies, int. al. in the form of standard tables and atlases, are available for assessing the normal skeletal maturation of children and adolescents. It was the object of the present study to assess the applicability of various foreign systems on a Danish normal series, to investigate the value of skeletal maturity as a parameter of the children's biological age, and lastly to assess whether differences in social circumstances influenced skeletal maturation. As it has been demonstrated that skeletal maturation may take place at different rates in different environments and at different times, it cannot be taken for granted that foreign norms are applicable unmodified in Denmark.

It is of practical importance to be able to determine the skeletal age and thus the stage of general physical development in conditions and diseases which entail disturbances of growth and maturation, partly because skeletal age is an important diagnostic aid and partly because it is a criterion which can tell us whether an instituted treatment is working.

It was decided to include children and adolescents in the age range 7–18 years, i.e. the ages before, during and after puberty because it is particularly within these age groups that children present problems concerning growth and maturation and because in the younger age groups height is quite a good standard of development.

girls respectively the onsets and sequence of the ossification centres, the times and sequence of epiphyseal fusion with the shaft and the spans from the onset of ossification until the process has been completed. The figures are derived from the study of Stuart Pyle, Cornoni & Reed which is the most comprehensive one.

At birth the hand and wrist show ossification centres only in the diaphyses of the metacarpal and phalangeal bones. In the course of the first 6 or 7 years of life 28 new ossification centres are formed 7 to become the carpal bones, 2 to become the distal epiphyses of the radius and ulna, and 19 at the sites of the epiphyses of the metacarpal and phalangeal bones. The adductor sesamoid

of the thumb does not form until towards puberty. The sequence in which the ossification centres appear differs significantly from that in which bone formation is completed (Stuart, Pyle, Cornoni & Reed).

The maturation of the hand and wrist bones is completed, according to Table 1, in boys roughly in the following sequence and at the following times: carpal bones $15^{8}/_{12}$ years, distal phalanges $15^{9}/_{12}$ years, proximal and middle phalanges $15^{11}/_{12}$ years, metacarpal bones $16^{7}/_{12}$ years, and radius 17 $/_{12}$ years.

The maturation of the same bones in girls is completed as follows (Table 2): distal phalanges $13^{2}/_{12}$ years, carpal bones $13^{3}/_{12}$ years, proximal phalanges $13^{9}/_{12}$ years, middle phalanges

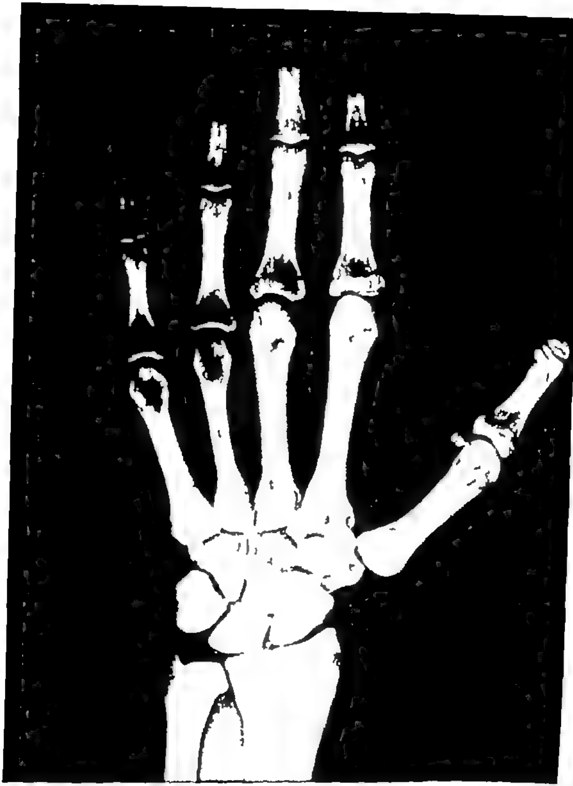
of the thumb does not form until towards puberty The sequence in which the ossification centres appear *differs* significantly from that in which bone formation is completed (Stuart, Pyle, Cornoni & Reed)

The maturation of the hand and wrist bones is completed, according to Table 1 in boys roughly in the following sequence and at the following times carpal bones $15^{9}/_{12}$ years, distal phalanges $15^{10}/_{12}$ years, proximal and middle phalanges $15^{11}/_{12}$ years, metacarpal bones $16^{3}/_{12}$ years, and radius $17^{4}/_{12}$ years.

The maturation of the same bones in girls is completed as follows (Table 2) distal phalanges $13^{7}/_{12}$ years, carpal bones $13^{9}/_{12}$ years, proximal phalanges $13^{9}/_{12}$ years, middle phalanges



F g 11

X ray film of hand and wrist showing the final hand sk leton

61 % of the boys showed a sequence of ossification as described by Greulich & Pyle (1959) This may presumably be explained largely by the fact that the children of this study were from the lower middle class, whereas the children of Greulich & Pyle s material were in the best conceivable social environment.

Garn & Rohmann (1960 a) set up their own ossification sequence. On comparison with Greulich & Pyle s (1959) Pyle & Sontag's, and Stuart & Stevenson s they found a high positive correlation between the various sequences (coefficient of correlation 0.9)

Finding a high correlation between the appearance of the various round bones as well as between the appearance of the epiphyses of the short bones, Robinow suggested that in assessing skeletal maturity the skeletal age of the round as well as of the short bones should be determined.

The fact that skeletal maturation takes place according to a fairly well-defined pattern has inspired the setting up of various systems for determining skeletal age. The maturation process is roughly concurrent in all parts of the skeleton. Some authors have preferred letting the bones of the hand represent skeletal development, while others have studied skeletal maturation in the foot, knee, or hip. Finally one side of the entire skeleton has been used in working out a system for assessing skeletal age.

Below a number of these studies will be reviewed, giving most attention to the two systems which were used as a basis for comparison in the present study Thereafter a number of older and more recent studies will be briefly mentioned.

Systems for Assessing Skeletal Age Based Upon Ossification Centres in the Hand and Wrist

T W Todd's Atlas

In 1926 T W Todd, Western Reserve University School of Medicine, Cleveland, Ohio, started a longitudinal study of unselected children from a school. During the first year the study comprised 800 children, during the second year 400 during the third year 200 during the fourth year 85 fifth year 45 sixth year 25 and seventh year 15 This experiment was carried through, but when Todd observed the trend, he felt that a study of selected children would be preferable.

In 1931 Todd started a comprehensive, accurately planned survey on the growth and development of normal children and worked on this project until his death in 1938 Thereafter it was continued, in charge of W W Greulich, and was completed in 1942 as originally planned by Todd. The expenses of the entire project were defrayed by the Brush Foundation, and it is usually known as the Brush Foundation study Concurrently with the study of the selected Brush Foundation children, Todd carried out several cross-sectional studies of children from a socially poorer environment.

Selection of Children. A total of 4500 children were included. They had been selected by paediatricians who had

$13^{10}/_{12}$ years, metacarpal bones $14^{2}/_{12}$ years, and radius $16^{8}/_{12}$ years. These figures are the results of a longitudinal study of 66 boys and 67 girls performed in the *Harvard School of Public Health* during the period 1930–1956 The children were born in a Boston hospital, they were healthy and their parents were of Northern European descent. Otherwise, there was no special selection.

The period which elapses from the first until the last epiphysis in the hand closes varies from 1 to 4 years (Garn Rohmann & Apfelbaum) Lavine, Moss & Noback (1962) found this span to vary from 4 to 28 months. They X rayed 111 children every 3 months from the age of 9 to 16 years. Garn et al. X rayed the children only every 6–12 months, and this may well be the explanation why they found a wider range.

Chronological Difference in the Skeletal Maturation of Boys and Girls

Ossification centres appear earlier in girls than in boys. Pryor (1923) found the difference in skeletal maturation between the two sexes to be days during foetal life, months during the first years of life, and years during puberty These phenomena are apparent from Tables 1 and 2 The capitate and hamate bones, which appear during the first year of life, develop 2–4 weeks earlier in girls than in boys. The completion of the carpal, phalangeal and metacarpal bones occurs about 2 years earlier in girls than in boys.

It is apparent also from Tables 1 and 2 that the standard deviations of the onset, completion, and span of ossification are less for girls than for boys.

Sequence of Ossification

The ossification centres appear in a well-defined sequence, almost the same for boys and for girls (Pryor 1907 Greulich & Pyle 1959 Pyle, Stuart Cornoni & Reed Stuart, Pyle, Cornoni & Reed)

Pryor (1907) described various deviations from the usual sequence, but on analysing Pryor s material Greulich (1959) found that these deviations were mostly explicable by disease or poor social conditions.

The sequence in which the ossification centres appear is presumably genetically determined, the same deviations from the most common sequence of ossification being manifest within the same families (Pryor 1907 Reynolds 1943 Reynolds & Schoen 1947)

Snodgrasse et al. (1955) found a significantly larger number of abnormalities in the maturation of the hand skeleton among children with nutritional disturbances than among healthy children. Irregularities in the sequence of ossification are most common in the carpal bones, cf the higher standard deviations for ossification of the carpal bones than for ossification of the epiphyses (Tables 1 and 2) Garn & Rohmann (1960 b) studied the variability in the order of ossification in the hand Studying 2880 X ray films of 154 children in a longitudinal study they found that only 49 % of the girls and

61 % of the boys showed a sequence of ossification as described by Greulich & Pyle (1959) This may presumably be explained largely by the fact that the children of this study were from the lower middle class, whereas the children of Greulich & Pyle s material were in the best conceivable social environment.

Garn & Rohmann (1960 a) set up their own ossification sequence. On comparison with Greulich & Pyle s (1959) Pyle & Sontag's, and Stuart & Stevenson s they found a high positive correlation between the various sequences (coefficient of correlation 0 9)

Finding a high correlation between the appearance of the various round bones as well as between the appearance of the epiphyses of the short bones, Robinow suggested that in assessing skeletal maturity the skeletal age of the round as well as of the short bones should be determined.

The fact that skeletal maturation takes place according to a fairly well-defined pattern has inspired the setting up of various systems for determining skeletal age. The maturation process is roughly concurrent in all parts of the skeleton. Some authors have preferred letting the bones of the hand represent skeletal development, while others have studied skeletal maturation in the foot knee, or hip. Finally one side of the entire skeleton has been used in working out a system for assessing skeletal age.

Below a number of these studies will be reviewed, giving most attention to the two systems which were used as a basis for comparison in the present study Thereafter a number of older and more recent studies will be briefly mentioned.

Systems for Assessing Skeletal Age Based Upon Ossification Centres in the Hand and Wrist

T W Todd's Atlas

In 1926 T W Todd, Western Reserve University School of Medicine, Cleveland Ohio started a longitudinal study of unselected children from a school. During the first year the study comprised 800 children, during the second year 400, during the third year 200 during the fourth year 85 fifth year 45, sixth year 25 and seventh year 13 This experiment was carried through, but when Todd observed the trend, he felt that a study of selected children would be preferable.

In 1931 Todd started a comprehensive, accurately planned survey on the growth and development of normal children and worked on this project until his death in 1938. Thereafter it was continued, in charge of W W Greulich, and was completed in 1942 as originally planned by Todd. The expenses of the entire project were defrayed by the Brush Foundation, and it is usually known as the Brush Foundation study Concurrently with the study of the selected Brush Foundation children, Todd carried out several cross-sectional studies of children from a socially poorer environment.

Selection of Children. A total of 4500 children were included. They had been selected by paediatricians who had

made sure that the children were not suffering from any physical or mental defects. The parents had given their permission for the children to take part in the project until it was finished In other words, this was a longitudinal survey

The criteria in respect to the parents, for including the children in the project were that the parents were interested in their children's physical well-being and mental development and that they took the time to act in accordance with this attitude

All the included children were from homes which were above the average educational and economic level but this had not been a condition All the children were white, of Northern European descent

The investigation comprised children in the age range 3 months to 19 years. During the first year of life the children were examined at 3-month intervals, later every 6 months. The examination consisted in X raying the left hand elbow shoulder foot, knee, and hip. Furthermore, measurement of height and other anthropometric measurements, i.e. of sitting height, arm length leg length circumference of skull, circumference of chest, and weighing Psychological tests were done, and the parents were questioned about the child's health since the last examination

Selection of Standards. Todd studied the skeletal maturation in all 6 above mentioned skeletal areas, but gave most attention to that of the hand skeleton

X rays of the hand skeleton were grouped by chronological age. Within each group the films were arranged in order according to the stage of maturity and the film which was most representative of the group was selected as a standard for the chronological age concerned. (Todd and his associates had previously studied the development of the hand skeleton on the films from the school study and found that for each individual bone the various indicators of maturity always appeared in the same sequence) Todd performed this selection of standards several times, first on the basis of the films from the 1926 school study later in 1931 and 1934 on the basis of films from the cross-sectional surveys, and finally in 1935 on the basis of films from the Brush Foundation study The last mentioned standards showed earlier skeletal maturation, explicable by the better social circumstances in which the children of the Brush Foundation study were raised.

Todd's Atlas of Skeletal Maturation of the Hand published in 1937 was based upon films of 1000 children of the Brush Foundation study and also upon films from the cross-sectional studies of children from a socially poorer environment. The standards for children during puberty were based almost exclusively upon films from the cross-sectional studies.

Greulich & Pyle's Atlas

After the investigation had been completed in 1942 Greulich & Pyle worked out a new atlas (1950) on the maturation of the hand skeleton according to the lines laid down by Todd However

they used exclusively films of children from the Brush Foundation study Each standard was selected from among 100 children of the same age and sex.

Whenever possible, films of the same child were used for successive standards. However the most representative film from the group was selected even though this interfered somewhat with the continuity from standard to standard. In 1959 they published a revised edition of the atlas which contained, for the boys, 2 extra standards for the ages 12 1/2 and 19 1/2 years and in which the standard for the age 13 1/2 years was replaced by a standard for the age 13 years. The 1959 edition was used in the present investigation.

The atlas gives, up to the age of 1 year standards for every 3 months, from the age of 1 to 5 years for every 6 months, and thereafter for each whole year For the time around puberty when maturation is faster a few extra standards have been inserted. This makes the time intervals between the standards somewhat irregular but the maturation is illustrated in a series of more continuous films. Figs. 4–11 show from the present material, examples of various stages of skeletal maturation. Each of the figures has been assessed on the basis of Greulich & Pyle's atlas, partly by the boys' and partly by the girls standards.

Use of the Atlas. When assessing the skeletal maturity of a child's hand, the standard which corresponds to the child's age and sex is looked up, and the film is compared with the standard concerned as well as with the standards for the ages just below and just above. In early childhood the comparison is based mainly upon the presence of the carpal bones. During puberty the thing to be considered is fusion of the epiphyses with the shafts, and at intermediate ages the comparison is done mainly by assessing the shape and mutual size of the bones.

In fact, the standards are directly applicable only for the material used in working out the atlas, as racial and environmental differences may influence skeletal maturation.

Greulich & Pyle's atlas gives for each picture a number of maturity indicators, i.e. descriptions of characteristic changes in the shape and fusion of the individual bones. These maturity indicators form the basis of a more detailed determination of skeletal age, each bone and epiphysis being assessed separately The atlas gives for each bone a skeletal age, if it is estimated to differ from the age of the entire standard.

Greulich himself assessed the skeletal age of children from the Brush Foundation study 60 children from each age group. He found that the mean standard deviation for boys in the age range 7–17 years was 11.0 months, i.e. that about two-thirds of the boys are of a skeletal age deviating by ± 11.0 months or less from the standard with which they ought to comply according to their age. One-third deviated by more than ± 11.0 months. As far as the girls are concerned, the mean standard deviation was ± 10.3 months. Greulich & Pyle (1959) mentioned that Stuart had studied the skeletal age of 50–60 children of each age group and sex in

made sure that the children were not suffering from any physical or mental defects. The parents had given their permission for the children to take part in the project until it was finished. In other words, this was a longitudinal survey

The criteria, in respect to the parents, for including the children in the project were that the parents were interested in their children's physical well-being and mental development and that they took the time to act in accordance with this attitude.

All the included children were from homes which were above the average educational and economic level but this had not been a condition All the children were white, of Northern European descent

The investigation comprised children in the age range 3 months to 19 years. During the first year of life the children were examined at 3-month intervals, later every 6 months. The examination consisted in X raying the left hand, elbow shoulder foot knee, and hip. Furthermore, measurement of height and other anthropometric measurements, i.e. of sitting height, arm length leg length circumference of skull circumference of chest, and weighing Psychological tests were done, and the parents were questioned about the child's health since the last examination.

Selection of Standards Todd studied the skeletal maturation in all 6 above-mentioned skeletal areas, but gave most attention to that of the hand skeleton

X rays of the hand skeleton were grouped by chronological age. Within each group the films were arranged in order according to the stage of maturity and the film which was most representative of the group was selected as a standard for the chronological age concerned. (Todd and his associates had previously studied the development of the hand skeleton on the films from the school study and found that for each individual bone the various indicators of maturity always appeared in the same sequence) Todd performed this selection of standards several times, first on the basis of the films from the 1926 school study later in 1931 and 1934 on the basis of films from the cross-sectional surveys, and finally in 1935 on the basis of films from the Brush Foundation study The last mentioned standards showed earlier skeletal maturation, explicable by the better social circumstances in which the children of the Brush Foundation study were raised.

Todd's Atlas of Skeletal Maturation of the Hand published in 1937 was based upon films of 1000 children of the Brush Foundation study and also upon films from the cross-sectional studies of children from a socially poorer environment The standards for children during puberty were based almost exclusively upon films from the cross-sectional studies.

Greulich & Pyle's Atlas

After the investigation had been completed in 1942 Greulich & Pyle worked out a new atlas (1950) on the maturation of the hand skeleton according to the lines laid down by Todd However

Kopczynska, therefore suggested working out standards for each country and pointed out that when skeletal age was assessed by foreign standards, the findings should be corrected on the basis of national standards.

J M Tanner & R H Whitehouse's System for Assessing the Maturity of the Hand Skeleton

A British method of assessing the maturity of the hand skeleton (Tanner & Whitehouse 1959 Tanner Whitehouse & Healy 1962) has been accessible in its present form since 1962.

Survey of the Working Out and Application of the Method For each individual bone of the hand and wrist Tanner & Whitehouse drew and described a number of maturity stages (cf. examples in Figs. 12–16) The drawings were made on the basis of a number of longitudinal X ray studies, especially of children from an orphanage near London. This project has so far been in progress for more than 10 years and is known as the Harpenden Growth Study

The number of maturity stages was reduced to 9 for the radius and to 8 for the other bones. The stages were arbitrary stages in the maturation from birth until the hand skeleton had completed its growth. The stages are denoted by letters, not ciphers, to avoid giving the impression that the stages are equally spaced.

For each stage of each bone 1 2, or praised girls and boys ranging in age from 1 month to 16 years.

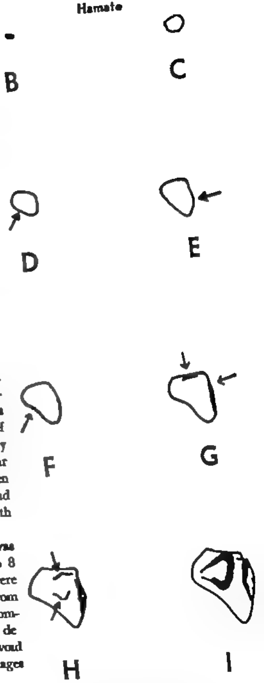


Fig 13

Stages in the maturation of the hamate from the appearance of the bone until its final stage. (Tanner & Whitehouse 1962)

Boston. He found that on the average the boys were retarded 2 months in relation to the children of the Brush Foundation study and that the mean standard deviation was 12.0 months. The girls were retarded by an average of 3 months, and the SD was 11 3 months.

It will be seen from Chapter 14 which deals with the influence of social factors upon skeletal maturation that Sutow (1952) used Greulich & Pyle's atlas *for assessing the skeletal maturation of Japanese children. Greulich* (1951) used the same atlas in a study of the skeletal maturation of school children on the isle of Guam, in a study of the skeletal development in American-born Japanese in the environs of San Fransisco (Greulich 1957) and in the study of Greulich et al (1953) of the skeletal age of Japanese children who had been exposed to the atomic bombing in Hiroshima.

In a cross-sectional study of 12 000 Polish boys and girls aged 7–16 years Kopczynska (1964) assessed the skeletal age by the Greulich & Pyle atlas method and related it to sex, height, weight, and social status. The skeletal maturation in the Polish children showed a pattern different from that in the American children upon whom Greulich & Pyle's atlas was based. The Polish girls aged 7–10 years showed the same *skeletal maturation as the* American ones, but older Polish girls were skeletally more advanced. The Polish boys, except for those who were 14 and 15 years of age, showed a retarded skeletal maturation. The difference between skeletal age and chronological age varied from age to age.

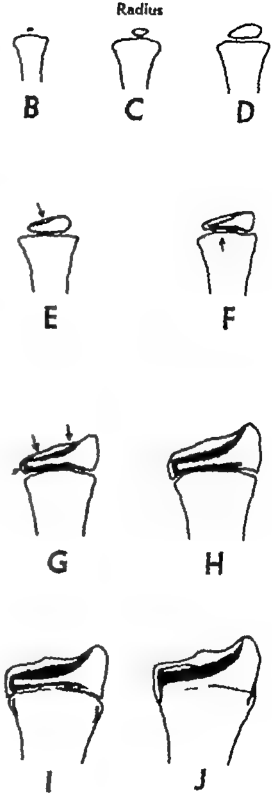

Fig 1

Stages in the maturation of the radius from the appearance of the bone until its final stage (Tanner & Whitehouse 1962)

Kopczynska, therefore, suggested working out standards for each country and pointed out that when skeletal age was assessed by foreign standards, the findings should be corrected on the basis of national standards.

J. M. Tanner & R. H. Whitehouse's System for Assessing the Maturity of the Hand Skeleton

A British method of assessing the maturity of the hand skeleton (Tanner & Whitehouse 1959, Tanner, Whitehouse & Healy 1962) has been accessible in its present form since 1962.

Survey of the Working Out and Application of the Method. For each individual bone of the hand and wrist Tanner & Whitehouse drew and described a number of maturity stages (cf. examples in Figs. 12–16). The drawings were made on the basis of a number of longitudinal X-ray studies, especially of children from an orphanage near London. This project has so far been in progress for more than 10 years and is known as the Harpenden Growth Study.

The number of maturity stages was reduced to 9 for the radius and to 8 for the other bones. The stages were arbitrary stages in the maturation from birth until the hand skeleton had completed its growth. The stages are denoted by letters, not ciphers, to avoid giving the impression that the stages are equally spaced.

For each stage of each bone 1, 2 or prised girls and boys ranging in age from 1 month to 16 years.

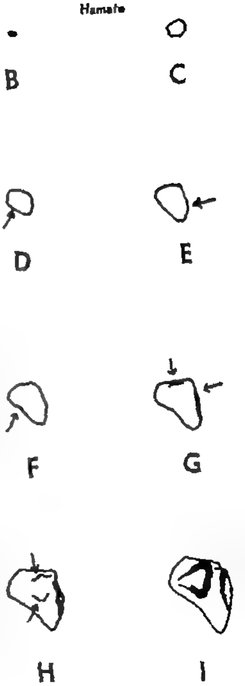

Fig. 13

Stages in the maturation of the hamate from the appearance of the bone until its final stage. (Tanner & Whitehouse 1962).

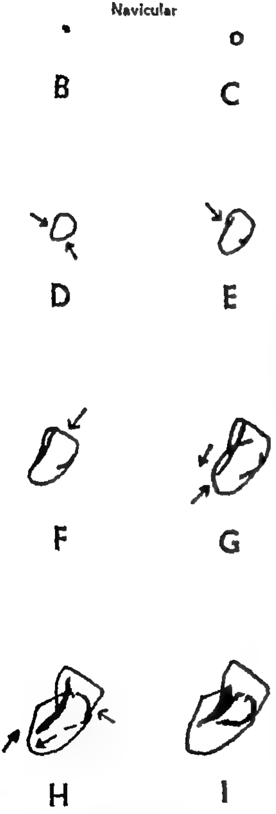

Fig 14

Stages in the maturation of the navicular from the appearance of the bone until its final stage (Tanner & Whitehouse 1962)

3 criteria have been described If only *one criterion is* given it has to be met if the bone is to be assessed as having reached the stage concerned If 2 criteria are given only one has to be met If 3 criteria are given 2 have to be met if the bone is to have reached the stage concerned Before a bone can be said to have reached a given stage, the first stated criterion of the preceding stage must also have been satisfied. The descriptions of the criteria are supplemented by drawings.

The criteria include the following factors (1) presence or absence of ossification centres, (2) closure of epiphyses, (3) relative sizes of ossification centres and relative distances between bones, (4) whether or not the bones are in contact and if so whether the contact is at a point or along a surface The measurements of item (3) sometimes require the use of a simple pair of dividers.

Scores were given for each developmental stage for each bone 0 when the ossification centre was not yet visible and 100 when the bone had reached its final stage

The score for the intermediate stages was calculated in such a way that the total score for the bones was given minimum variance for the individual hand According to this preliminary rating system a hand in the final stage attained 2800 the hand and wrist consisting of 28 bones and sesamoid bones. The calculations concerning the rating were based upon a cross-sectional study of about 2600 British children of 6 groups believed to be representative of an average socio-economic level in the British population This material [illegible]

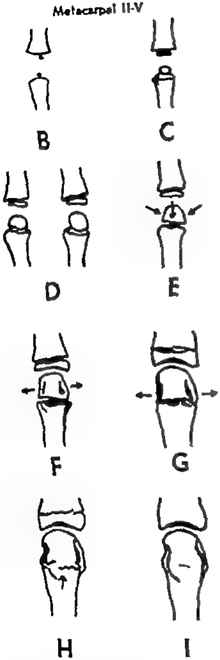

Fig. 1

Stages in the maturation of the 2nd–5th metacarpals from the appearance of the head of the metacarpal until its fusion with the diaphysis. (Tanner & Whitehouse 1962)

It was endeavoured to assess whether it was justified to let all bones contribute an equal share to the total skeletal age, but this problem could not be solved by statistical calculations on the correlations between the bones.

On the basis of purely biological considerations, it was then necessary to form an estimate of how the bones were to be combined—according to their role in the development of the entire hand skeleton.

The biological considerations were that a simple average of all the bones would be overweighted by the large number of metacarpal and phalangeal bones which develop almost simultaneously and in approximately the same way. Therefore, metacarpal bones 2 and 4 and the corresponding phalangeal bones were left out of the system which then included 20 bones

radius, distal epiphysis

As it was presumed that the development of the long and of the round bones was controlled by different factors, the rating system was worked out in the way that these two sets of bones

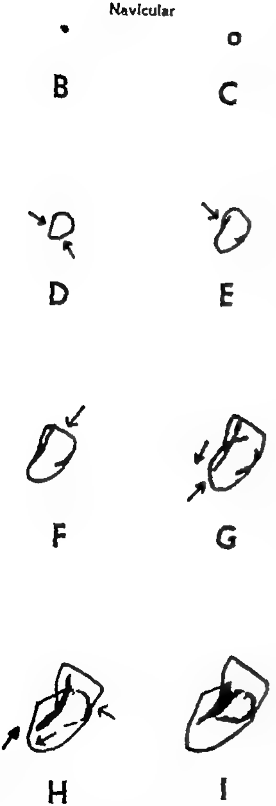

Fig 14
Stages in the maturation of the navicular from the appearance of the bone until its final stage (Tanner & Whitehouse 1962)

3 criteria have been described. If only one criterion is given it has to be met if the bone is to be assessed as having reached the stage concerned. If 2 criteria are given only one has to be met. If 3 criteria are given 2 have to be met if the bone is to have reached the stage concerned. Before a bone can be said to have reached a given stage, the first stated criterion of the preceding stage must also have been satisfied. The descriptions of the criteria are supplemented by drawings.

The criteria include the following factors (1) presence or absence of ossification centres, (2) closure of epiphyses, (3) relative sizes of ossification centres and relative distances between bones, (4) whether or not the bones are in contact and if so whether the contact is at a point or along a surface. The measurements of item (3) sometimes require the use of a simple pair of dividers.

Scores were given for each developmental stage for each bone 0 when the ossification centre was not yet visible and 100 when the bone had reached its final stage.

The score for the intermediate stages was calculated in such a way that the total score for the bones was given minimum variance for the individual hand. According to this preliminary rating system a hand in the final stage attained 2800 the hand and wrist consisting of 28 bones and sesamoid bones. The calculations concerning the rating were based upon a cross-sectional study of about 2600 British children of 6 groups believed to be representative of an average socio-economic level in the British population. This material com

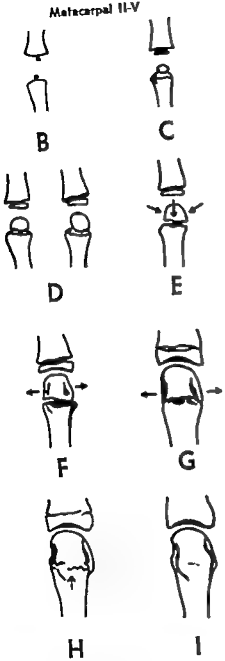

Fig 15

Stages in the maturation of the 2nd-5th metacarpals from the appearance of the head of the metacarpal until its fusion with the diaphysis. (Tanner & Whitehouse 1962)

It was endeavoured to assess whether it was justified to let all bones contribute an equal share to the total skeletal age, but this problem could not be solved by statistical calculations on the correlations between the bones.

On the basis of purely biological considerations, it was then necessary to form an estimate of how the bones were to be combined—according to their role in the development of the entire hand skeleton.

The biological considerations were that a simple average of all the bones would be overweighted by the large number of metacarpal and phalangeal bones which develop almost simultaneously and in approximately the same way. Therefore, metacarpal bones 2 and 4 and the corresponding phalangeal bones were left out of the system which then included 20 bones

radius, distal epiphysis
ulna, distal epiphysis

greater multangular
lesser multangular

As it was presumed that the development of the long and of the round bones was controlled by different factors, the rating system was worked out in the way that these two sets of bones

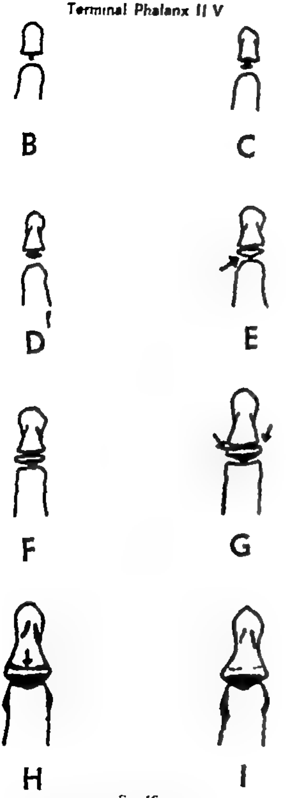

Fig 16

Stages in the maturation of the distal phalanges II–V from the appearance of the epiphysis until its fusion with the diaphysis (Tanner & Whitehouse 1962)

contributed 50 % each to the score in the mature hand skeleton, and so that each set of bones may be assessed separately by some conversions. Thus, the 7 carpal bones each contribute by approx 7 % of the development of the entire hand the ulna and radius each by 10 % and the 1st 3rd and *5th metacarpal bone with corresponding* phalangeal bones each by 10 %

In the assessment of the skeletal age of a hand, the maturity stages of the 20 named bones are estimated Each stage is rated according to a scoring system worked out according to the above mentioned lines. The scores are added and looked up in a table (listing scores from 0–1000) which converts the scores to skeletal ages. The scale closes as far as the boys are concerned at a skeletal age of 18 years and for the girls at 17 years.

Since, however the material comprises only children up to the age of 16 years, and since the named limits were fixed, the scale is inaccurate for the oldest age groups, as also pointed out by Tanner & Whitehouse.

When the scores are converted to a log scale, the diagrams show rapid growth in the youngest age groups, slower from 7 to 10 years of age, rapid around puberty and then again slow

Plotting skeletal ages against chronological ages gives a rectilinear course of the curve, and the percentiles run parallel with this line from about 5 years of age and onwards. The distance between the 10 % and 90 % percentile for a given chronological age may be read from the curve as about 32 months. This corresponds to a SD of 12–12 5 months.

Other Studies of the Maturation of the Hand Skeleton

Behrendsen (1897) and *Ranke* (1898) published X rays of the hand skeleton of boys and girls of various ages, described the changes in development from age to age, and pointed out that the number of ossification centres in the hand skeleton seen by X-rays express roughly the child's age.

Holmgren (1910) from X-rays of the hands of 115 children with Graves disease, compared the skeletal maturity with reported findings concerning the time of epiphyseal fusion with the diaphyses. He concluded that the children of his study showed very early maturation.

In 1921 *Stettner* published a paper on the normal and abnormal development of the hand skeleton. He related skeletal maturity to height, sex, and social circumstances. The study showed that children from rural districts were skeletally retarded compared with children from urban areas. He confirmed the marked variation in the times of appearance of the individual ossification centres.

Siegert's "Atlas der normalen Ossifikation der menschlichen Hand" was published in Germany in 1935. This was the first atlas to illustrate the maturation of the hand skeleton. He made a single examination by X-ray of each of 244 girls and 200 boys who were carefully selected for a cross-sectional study. He found the sequence in which the bones ossify to be fairly regular and similar in both sexes and ossification to occur earlier in girls than in boys. The atlas comprised 130 X-rays out of a total of 444. Thus, in fact this atlas is a number of case reports demonstrating the skeletal maturation from 0 to 12 years. Siegert believed that a given stage of maturity in a normal child corresponded to a given age. Todd on the other hand realized that there are normal variations which may be described by mean values with standard deviations.

Flory's Atlas

Flory in 1936, published an atlas of the maturation of the hand skeleton. He used 5000 X-rays taken in a mixed longitudinal cross-sectional study of children aged 5–17 years from the Chicago Laboratory School. These children were above average in intelligence as well as in respect to parents income and social status. In addition, the material included 300 X rays of children aged 0–5 years from 2 Chicago hospitals and 225 X-rays of adolescents aged 18–20 years from the University of Chicago, Junior College.

It had first been Flory's intention to employ planimetry of the bones in the carpal region for working out a system for estimating skeletal maturation. However after having consulted with Todd in 1931 he altered his method and used, like Todd, the Inspection method. He selected his standards by the same pattern as Todd choosing from among 100 X-rays of children of the same age and sex, the film which best represented the average as a standard. The standards were accompanied by descriptions including the same criteria which Todd had suggested.

Flory demonstrated that the correlation between physical maturity and

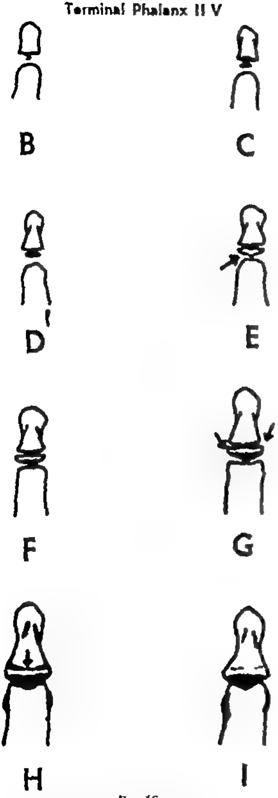

Fig 16

Stages in the maturation of the distal phalanges II–V from the appearance of the epiphysis until its fusion with the diaphysis (Tanner & Whitehouse 1962)

contributed 50 % each to the score in the mature hand skeleton and so that each set of bones may be assessed separately by some conversions. Thus, the 7 carpal bones each contribute by approx. 7 % of the development of the entire hand, the ulna and radius each by 10 % and the 1st 3rd and 5th metacarpal bone with corresponding phalangeal bones each by 10 %

In the assessment of the skeletal age of a hand, the maturity stages of the 20 named bones are estimated Each stage is rated according to a scoring system worked out according to the above-mentioned lines. The scores are added and looked up in a table (listing scores from 0–1000) which converts the scores to skeletal ages. The scale closes as far as the boys are concerned at a skeletal age of 18 years and for the girls at 17 years.

Since, however the material comprises only children up to the age of 16 years, and since the named limits were fixed, the scale is inaccurate for the oldest age groups, as also pointed out by Tanner & Whitehouse.

When the scores are converted to *a log scale, the diagrams show rapid* growth in the youngest age groups, slower from 7 to 10 years of age, rapid around puberty and then again slow

Plotting skeletal ages against chronological ages gives a rectilinear course of the curve, and the percentiles run parallel with this line from about 5 years of age and onwards. The distance between the 10 % and 90 % percentile for a given chronological age may be read from the curve as about 32 months. This corresponds to a SD of 12–12.5 months.

technically poor. As there is a 1 year interval between the standards after the age of 4 years, there are too few films to show the rapid development during puberty.

Systems for Assessing Skeletal Age Based Upon Ossification Centres in the Foot, Knee or Hip

The large material from the Brush Foundation study was further utilized when *Pyle & Hoerr* (1955) published an atlas of the *skeletal maturation of the knee*.

As a further result of the same comprehensive study *Hoerr, Pyle & Francis'* atlas of *skeletal maturation of the foot and ankle* appeared in 1962. This atlas differs from the hand atlas in having only a single set of standards common to boys and girls. With each standard the skeletal ages are given for boys and girls respectively. As in Greulich & Pyle's atlas maturity indicators are described for each bone. Much earlier Bade (1899) and Hasselwander (1903) had described the maturation of the foot skeleton during foetal life and early childhood. Both pointed out marked variations in the times of appearance of the individual ossification centres.

In 1937 *Acheson* published his study on *skeletal maturation of the hip*. His method was derived from the study of 6500 X-rays from the Brush Foundation study and of 6000 X-rays of children from the Institute of Social Medicine, Oxford, England, and is called the Oxford method.

For each ossification centre in the hip Acheson listed a number of maturity indicators, i.e. definitions of easily demonstrable changes in the shape and degree of fusion of the bones. He rated the individual ossification centres according to the stage of maturation they had reached and worked out a table which expresses, in percentages for a given overall score, the maturation of the hip concerned.

This method has the advantage that indicators appear in the hip over a large number of years. For instance, during the first 6 months of life a larger number of indicators appear in the hip than in any other part of the skeleton, and new indicators continue to appear after other parts of the skeleton have reached their final stage.

The drawbacks of the method are that the study involves irradiation of the gonads and that the reading of the X-rays is time-consuming and requires some experience.

The accuracy in reading the films is the same with Greulich & Pyle's method as with the Oxford method, there being no significant difference between the correlation coefficients for age and skeletal maturity by the two methods. Acheson recommends Greulich & Pyle's atlas for clinical use, but feels that the Oxford method is preferable for research purposes, because it has its own scale.

System for Assessing Skeletal Age Based Upon Ossification Centres in Half the Peripheral Skeleton

In 1964 *Elgenmark*, in Sweden, published a study of the *normal maturation of the ossification centres in children aged 1 month to 5 years.*

skeletal age is highest when the skeletal age is measured by the inspection method (*atlas method*) *less marked* when measuring the ossification ratio (the relation between the length and width of various bones) and least in the planimetry method The reason why the estimation of skeletal age is less accurate when it is determined by the ossification ratio or by planimetry *is presumably* that these methods do not contain criteria for differentiation. These methods are least accurate during the years of and after puberty

However Flory's material was heterogeneous, *it is not sufficiently described*, his X rays are technically poor and the hand is incompletely shown in some of the exposures.

In 1950 *Speijer* in Holland, published an atlas on the maturation of the hand skeleton He had performed a cross-sectional study of a total of *360 healthy children in Leiden. The* material comprised 10 boys and 10 girls for each year of age from 3 to 20 years and was drawn from nursery and other schools as well as students and apprentices.

The left hand and hip were X rayed. For each group of 10 he chose the picture which was judged the best representative of the group and also those which showed the most advanced and the most retarded skeletal maturation. Thus, for each chronological age *Speijer presented 3 X rays to demon*strate the degree of maturity and variations thereof Comparing the X rays for the different ages, *he found that* for boys in the age range 3–9 years there was a normal variation of ± 2 years, in the age range 9–14 years a variation of ± 4 years, and at higher ages again a variation of ± 2 years. *As far as the girls were concerned, the* variation was said to be fairly constant at ± 2 years.

The material is small and could not be analysed statistically No other investigators have attempted to test the method, and the quality of the X rays is not particularly good.

In 1960 the German authors *Schmid & Moll* published their atlas on the normal and abnormal development of the hand skeleton. This atlas was worked out on the basis of a cross-*sectional study of 4000 children aged* 0–14 years, half of whom were healthy Up to the age of 1 year the children were *divided* into age groups *of 3* months, from 1–4 years into age groups of 6 months, and thereafter into age groups of 12 months.

On each film measurements were *made by planimetry of the epiphyses* of the carpal bones, the distal epiphyses of the ulna and radius, and the epiphysis of the 1st metacarpal bone.

The atlas presents for each group the average example together with the most advanced and most retarded ones. The means, standard errors, and standard deviations are tabulated. Schmid & Moll maintain that the planimetry method shows a negligible difference in maturation of boys and girls and therefore give only one set of standards. The planimetry method does not reveal the time difference in maturation of up to 2 years between girls *and boys, and* Schmid & Moll do not take this difference into account Therefore, the method must be inaccurate. The pictures *in the atlas are*

technically poor As there is a 1 year interval between the standards after the age of 4 years, there are too few films to show the rapid development during puberty

Systems for Assessing Skeletal Age Based Upon Ossification Centres in the Foot Knee or Hip

The large material from the Brush Foundation study was further utilized when *Pyle & Hoerr* (1955) published an atlas of the *skeletal maturation of the knee*

As a further result of the same comprehensive study Hoerr Pyle & Francis' atlas of *skeletal maturation of the foot and ankle* appeared in 1962. This atlas differs from the hand atlas in having only a single set of standards common to boys and girls. With each standard the skeletal ages are given for boys and girls respectively As in Greulich & Pyle's atlas maturity indicators are described for each bone. Much earlier Bade (1899) and Hasselwander (1903) had described the maturation of the foot skeleton during foetal life and early childhood. Both pointed out marked variations in the times of appearance of the individual ossification centres.

In 1957 *Acheson* published his study on *skeletal maturation of the hip*. His method was derived from the study of 8500 X-rays from the Brush Foundation study and of 6000 X-rays of children from the Institute of Social Medicine, Oxford, England, and is called the Oxford method.

For each ossification centre in the hip Acheson listed a number of maturity indicators, i.e. definitions of easily demonstrable changes in the shape and degree of fusion of the bones. He rated the individual ossification centres according to the stage of maturation they had reached and worked out a table which expresses, in percentages for a given overall score, the maturation of the hip concerned.

This method has the advantage that indicators appear in the hip over a large number of years. For instance, during the first 8 months of life a larger number of indicators appear in the hip than in any other part of the skeleton, and new indicators continue to appear after other parts of the skeleton have reached their final stage.

The drawbacks of the method are that the study involves irradiation of the gonads and that the reading of the X-rays is time-consuming and requires some experience.

The accuracy in reading the films is the same with Greulich & Pyle's method as with the Oxford method, there being no significant difference between the correlation coefficients for age and skeletal maturity by the two methods. Acheson recommends Greulich & Pyle's atlas for clinical use, but feels that the Oxford method is preferable for research purposes, because it has its own scale.

System for Assessing Skeletal Age Based Upon Ossification Centres in Half the Peripheral Skeleton

In 1964 *Elgenmark* in Sweden, published a study of the *normal maturation of the ossification centres in children aged 1 month to 5 years*.

He wanted to elucidate the time of appearance of the various ossification centres in Swedish children. His material comprised 429 boys and 423 girls from Stockholm and environs, selected among children who had been examined or treated at the paediatric hospital "Samariten" in Stockholm. All the children were healthy and in good nutritional state. A small proportion were examined several times. The study was planned as a cross-sectional survey. The children were divided into 1 month groups up to 1 year of age and thereafter into 3 month groups.

The investigation consisted in X-raying the left half of the body (in 59 cases the entire skeleton was X-rayed) and in measuring height and weight. For each child Elgenmark counted how many ossification centres, out of 68 possible, were present in one half of the skeleton. For each ossification centre he stated the earliest times of appearance and the time at which the ossification centre appeared in 25 % in 50 % and in 100 % of the cases.

In addition he set up for each age, tables showing how many ossification centres were present, expressed by the mean M ± 1, 2, 2 ½ and 3 standard deviations. The number of ossification centres too was then related to height. Elgenmark found that ossification centres appeared earlier in girls than in boys. Up to the age of 8 months the difference averaged 2 months and thereafter increased.

Comparison of the times of appearance of symmetrical ossification centres in 59 children revealed but slight differences. In boys there was no difference between the number of cases in which the right and left half of the skeleton was first mature. In girls there were 9 cases of earlier development of an ossification centre on the left, in 3 cases on the right. This indicates that it is immaterial whether the right or the left side is X-rayed when assessing a person's skeletal age. Torgersen (1951) X-rayed both hands of 404 children under 9 years of age. He found that in 60 cases the right side was slightly advanced in development, in 95 cases the left side was more advanced, while in the remainder there was no demonstrable difference. He concluded that the difference was too small to constitute a source of error in estimating skeletal age. Similarly Dreizen et al. (1957 a) found the difference in skeletal age of the two hands of 450 children to exceed 3 months in only 13%. The greatest difference was 6 months, found in only 1.5 %. This has been confirmed by Greulich & Pyle (1959).

Elgenmark also found a highly positive correlation between age and the number of ossification centres as well as between height and the number of ossification centres and between body weight and the number of ossification centres. By means of the tables it ought to be possible to decide whether the skeletal development of a child is normal if the child is of the same race and is living under the same circumstances as the children of the experimental series.

Elgenmark pointed out that the results should be considered with some reservation because the material was fairly small and because the children's

social status in relation to the optimum was not known.

Hoerr, Pyle & Francis found the ossification centres in Elgenmark's material to appear later than in their own material of well-circumstanced children from the Brush Foundation study. Moreover, the variation in the time of their appearance proved to be greater in the former.

Åkerlund in 1918, published an atlas on skeletal maturation based upon a series of 56 healthy children aged 8–14 years in Stockholm schools. These children were from low social strata. X-rays *of the hand, foot, and elbow for* boys and girls respectively are grouped by age and within each one year group by skeletal maturity. Åkerlund observed individual differences in the sequence of maturation of the various bones. He believed that the hand and wrist were not sufficiently representative of skeletal maturation.

Suitability of Various Regions for Assessing Skeletal Maturity

Todd studying skeletal maturation in the 6 areas hand, elbow shoulder foot, knee, and hip in children from the Brush Foundation study arrived at the result that in healthy children raised under optimum conditions, the skeleton in all 6 areas has reached the same degree of maturity.

When the same investigation was applied to X-rays from school studies, the lowest standard deviations were found in assessment of skeletal maturation of the hand. Therefore, the hand was that part of the skeleton which gave the most satisfactory results, poorer results being found for the foot, knee, elbow shoulder and hip in the named order. According to the findings of Garn & Rohmann (1960 b) assessment of skeletal maturation in the hand and foot does not afford more accuracy than assessment of the hand alone. These results are in keeping with the presumption that the hand and wrist must afford a representative picture of the entire skeletal maturation, as this area contains so many ossification centres. Since, furthermore, the hand is easy to X-ray and since it may be X-rayed without irradiation of other parts of the body, it is justified that skeletal maturation is most frequently studied in the hand.

Garn, Silverman & Rohman (1964) are working on a *system for* assessing skeletal age which takes into account that certain bones are of greater importance than others in skeletal age assessment. This was pointed out by Todd who, however, did not submit any documentation.

In order to find those ossification centres which are of most importance in a correct assessment of skeletal maturity, Garn et al., in a longitudinal study determined the time correlation between the appearance of 52 ossification centres in the hand and foot. They found 10 ossification centres in the hand and 9 in the foot to be of greater importance than the remainder. The 10 centres in the hand were among the epiphyses of the metacarpal and phalangeal bones of the 2nd–5th fingers, all of which were of greater importance in determining skeletal age than were the ossification centres in the foot.

He wanted to elucidate the time of appearance of the various ossification centres in Swedish children His material comprised 429 boys and 423 girls from Stockholm and environs, selected among children who had been examined or treated at the paediatric hospital Samariten in Stockholm All the children were healthy and in good nutritional state. A small proportion were examined several times. The study was planned as a cross-sectional survey The children were divided into 1-month groups up to 1 year of age and thereafter into 3-month groups.

The investigation consisted in X raying the left half of the body (in 59 cases the entire skeleton was X-rayed) and in measuring height and weight. For each child Elgenmark counted how many ossification centres, out of 68 possible, were present in one half of the skeleton. For each ossification centre he stated the earliest times of appearance and the time at which the ossification centre appeared in 25 %, in 50 % and in 100 % of the cases.

In addition, he set up for each age, tables showing how many ossification centres were present, expressed by the mean M ± 1 2, 2 ¹/₂ and 3 standard deviations. The number of ossification centres too was then related to height. Elgenmark found that ossification centres appeared earlier in girls than in boys. Up to the age of 8 months the difference averaged 2 months and thereafter increased.

Comparison of the times of appearance of symmetrical ossification centres in 59 children revealed but slight differences. In boys there was no difference between the number of cases in which the right and left half of the skeleton was first mature. In girls there were 9 cases of earlier development of an ossification centre on the left, in 3 cases on the right. This indicates that it is immaterial whether the right or the left side is X rayed when assessing a person's skeletal age. Torgersen (1951) X rayed both hands of 404 children under 8 years of age. He found that in 60 cases the right side was slightly advanced in development, in 95 cases the left side was more advanced, while in the remainder there was no demonstrable difference. He concluded that the difference was too small to constitute a source of error in estimating skeletal age. Similarly Dreizen et al (1957 a) found the difference in skeletal age of the two hands of 450 children to exceed 3 months in only 13% The greatest difference was 6 months, found in only 1.5 % This has been confirmed by Greulich & Pyle (1959)

Elgenmark also found a highly positive correlation between age and the number of ossification centres as well as between height and the number of ossification centres and between body weight and the number of ossification centres. By means of the tables it ought to be possible to decide whether the skeletal development of a child is normal if the child is of the same race and is living under the same circumstances as the children of the experimental series.

Elgenmark pointed out that the results should be considered with some reservation because the material was fairly small and because the children's

social status in relation to the optimum was not known.

Hoerr Pyle & Francis found the ossification centres in Elgenmark's material to appear later than in their own material of well-circumstanced children from the Brush Foundation study. Moreover the variation in the time of their appearance proved to be greater in the former.

Akerlund in 1918, published an atlas on skeletal maturation based upon a series of 56 healthy children aged 8–14 years in Stockholm schools. These children were from low social strata. X-rays of the hand, foot, and elbow for boys and girls respectively are grouped by age and within each one year group by skeletal maturity. Akerlund observed individual differences in the sequence of maturation of the various bones. He believed that the hand and wrist were not sufficiently representative of skeletal maturation.

Suitability of Various Regions for Assessing Skeletal Maturity

Todd, studying skeletal maturation in the 6 areas hand, elbow shoulder foot, knee, and hip in children from the Brush Foundation study arrived at the result that in healthy children raised under optimum conditions, the skeleton in all 6 areas has reached the same degree of maturity.

When the same investigation was applied to X-rays from school studies, the lowest standard deviations were found in assessment of skeletal maturation of the hand. Therefore, the hand was that part of the skeleton which gave the most satisfactory results, poorer results being found for the foot, knee, elbow shoulder and hip in the named order. According to the findings of Garn & Rohmann (1960 b) assessment of skeletal maturation in the hand and foot does not afford more accuracy than assessment of the hand alone. These results are in keeping with the presumption that the hand and wrist must afford a representative picture of the entire skeletal maturation, as this area contains so many ossification centres. Since, furthermore, the hand is easy to X-ray and since it may be X rayed without irradiation of other parts of the body it is justified that skeletal maturation is most frequently studied in the hand.

Garn, Silverman & Rohman (1964) are working on a system for assessing skeletal age which takes into account that certain bones are of greater importance than others in skeletal age assessment. This was pointed out by Todd who, however did not submit any documentation.

In order to find those ossification centres which are of most importance in a correct assessment of skeletal maturity Garn et al., in a longitudinal study determined the time correlation between the appearance of 52 ossification centres in the hand and foot. They found 10 ossification centres in the hand and 9 in the foot to be of greater importance than the remainder. The 10 centres in the hand were among the epiphyses of the metacarpal and phalangeal bones of the 2nd–5th fingers, all of which were of greater importance in determining skeletal age than were the ossification centres in the foot.

The carpal ossification centres were found to be of little importance in estimating skeletal age.

It is planned to include also ossification centres in the elbow, shoulder, knee, and hip in the study and to calculate the correlation between the closure of the various epiphyses in order to be able to select those centres which are of most importance in assessing skeletal age.

In the future it might be possible to concentrate on a few but important ossification centres and even obtain estimations more accurate than at present.

Systems for Assessing Stage of Sexual Maturation

Various systems for assessing stages of pubic hair and breast maturation will be reviewed below. The development is continuous, and the selected stages are defined arbitrarily. The various ways in which pubic hair maturation is described in stages are fairly consistent. The same applies to the ways of describing breast maturation. However the mere fact that different methods of assessment exist indicates that it is difficult to choose satisfactory maturational stages. If too many stages are used the classification may become inaccurate. If few stages are used, so that they may be clearly defined and easy to employ the classification may become so rough as to be of no practical interest.

It is much easier to describe the maturation when it is possible to use, instead of stages, direct measurements of the organs, e.g. of the penis and testes, or when it is possible to record the accurate time of an event, such as the menarche.

Boys

Greulich et al. (1942) have described the sexual maturation of boys by 5 stages (*maturity groups*).

1. Testes, penis, and scrotum as in early childhood. Vellus in the pubic region, no axillary hair.
2. Testes and penis a little larger. Longer slightly pigmented pubic hair at the base of the penis.
3. Testes and penis have increased in size. Slightly pigmented, straight somewhat coarser pubic hair. Axillary hair. Slightly pigmented hair on the upper lip.
4. Testes and penis somewhat larger. Dense, pigmented curled pubic hair in an area smaller than in an adult. Further growth of axillary hair and moustache.
5. Testes and penis as in an adult. Pubic hair of adult type, in some cases with extension along the linea alba. Axillary hair of adult type. Moustache as well as beard.

These maturity groups were selected after the study of photographs taken in longitudinal surveys.

Stolz & Stolz (1951), Reynolds & Wines (1951), Nicholson & Hanley (1953), Falkner (1962) and Tanner also use photographs in assessing the stage of sexual maturation in longitudinal studies on growth and development. This method does not give exact measures of the testes and penis as is also apparent from the classification. Only a few workers have used direct measurement of these organs (Reich 1924

From Hansen & With 1951 and Quaade 1955)

In the maturity groups of Greulich et al (1942) there is no distinct difference in the description of the pubic hair in stages 2 and 3 Quaade (1955) therefore, reduced the description of the *pubic hair maturation* to 4 stages

1 The infantile stage, i.e. vellus.
2 Scattered, straight, slightly pigmented pubic hair
3 Denser curled pigmented pubic hair in the area at the base of the penis.
4 Pubic hair spreading over the entire pubic triangle, in some cases also to the thighs and along the linea alba.

Reynolds & Wines (1951) describe the development of pubic hair in 5 stages

1 The infantile stage, vellus.
2 Scattered straight, pigmented pubic hair
3 Curled pigmented pubic hair
4 Fairly dense, curled pigmented hair but not of the extent seen in adults.
5 Pubic hair of adult type.

Falkner describes 6 stages, dividing Reynolds & Wines (1951) 5th stage into two, according to the extent of pubic hair

Tanner's classification is identical with Reynolds & Wines (1951)

Hansman & Maresh (1961) describe only the time of appearance of the pubic hair In the present study the author used Greulich et al's (1942) modified method for assessing pubic hair partly because it was used by Quaade (1955) in a Danish material which makes the results found in two Danish studies comparable, and partly because the stages are well-defined and fairly easy to employ

Girls

Breast maturation was described by Stratz (1904) by 4 stages

1 The infantile stage. Areola flat, nipple slightly prominent. No glandular tissue.
2 Prominence of areola and nipple and incipient development of glandular tissue.
3 Increased quantity of glandular and fatty tissue. Areola and nipple prominent, forming a separate mound above the general contour of the breast
4 Breast fully developed Areola on a level with the skin. Nipple more or less prominent.

Greulich et al (1938) refer to this description

Reynolds & Wines (1948) describe breast development in 5 stages

1 Infantile stage, elevation of the nipple.
2 Elevation of the nipple, areola, and breast.
3 Further growth and elevation of the breast and areola with no distinct separation of their contours.
4 Areola and nipple form a separate mound above the level of the breast
5 No separation of the contours of areola and breast, prominence of nipple.

Comparison of the two classifications shows that stages 2 and 3 of Reynolds

& Wines (1948) system correspond largely to stage 2 of Stratz.

Nicholson & Hanley used the classification of Stratz. Falkner described the breast development in 4 stages, but his stages are not as differentiated as Stratz' Tanner refers to Reynolds & Wines (1948) classification.

The present author used Stratz classification, partly because his stages are more clearly defined than Reynolds' & Wines' (1948) and accordingly easier to use, and partly because Stratz' classification was used by Quaade (1955) in a Danish material. This makes the results from the two Danish studies comparable.

The developmental pattern of pubic hair is the same in girls and boys, and the classifications given above for describing the maturation of pubic hair in boys apply also to girls.

The present author used Greulich et al.s (1942) modified method for the reasons stated in the section on boys.

1. The infantile stage, vellus.
2. Scattered, straight slightly pigmented pubic hair
3. Denser curled, pigmented pubic hair medially on the labia.
4. Pubic hair covering the entire pubic triangle, limited by a horizontal line superiorly

Extension to the linea alba occurs in 10 % of women and in 80 % of men (Thomas & Ferriman 1957)

From Hansen & With 1951 and Quaade 1955)

In the maturity groups of Greulich et al (1942) there is no distinct difference in the description of the pubic hair in stages 2 and 3 Quaade (1955) therefore, reduced the description of the *pubic hair maturation* to 4 stages

1 The infantile stage, i.e. vellus.
2. Scattered, straight, slightly pigmented pubic hair
3 Denser curled pigmented pubic hair in the area at the base of the penis.
4 Pubic hair spreading over the entire pubic triangle in some cases also to the thighs and along the linea alba.

Reynolds & Wines (1951) describe the development of pubic hair in 5 stages

1 The infantile stage, vellus.
2 Scattered straight pigmented pubic hair
3 Curled pigmented pubic hair
4 Fairly dense, curled pigmented hair but not of the extent seen in adults.
5 Pubic hair of adult type.

Falkner describes 6 stages, dividing Reynolds & Wines' (1951) 5th stage into two according to the extent of pubic hair

Tanner's classification is identical with Reynolds & Wines (1951)

Hansman & Maresh (1961) describe only the time of appearance of the pubic hair In the present study the author used Greulich et al.'s (1942) modified method for assessing pubic hair partly because it was used by Quaade (1955) in a Danish material, which makes the results found in two Danish studies comparable, and partly because the stages are well-defined and fairly easy to employ

Girls

Breast maturation was described by Stratz (1904) by 4 stages

1 The infantile stage. Areola flat, nipple slightly prominent. No glandular tissue.
2 *Prominence of areola and nipple* and incipient development of glandular tissue.
3 Increased quantity of glandular and fatty tissue. Areola and nipple prominent forming a separate mound above the general contour of the breast.
4 Breast fully developed. Areola on a level with the skin. Nipple more or less prominent.

Greulich et al. (1938) refer to this description.

Reynolds & Wines (1948) describe breast development in 5 stages

1 Infantile stage, elevation of the nipple.
2. Elevation of the nipple, areola and breast.
3 Further growth and elevation of the breast and areola with no distinct separation of their contours.
4 Areola and nipple form a separate mound above the level of the breast
5 No separation of the contours of areola and breast, prominence of nipple.

Comparison of the two classifications shows that stages 2 and 3 of Reynolds

all the children, 12 were excluded because of diseases such as diabetes mellitus, chronic pyelonephritis, bronchial asthma, history of poliomyelitis or tuberculosis, as the object was to assess the stage of maturation in children who were clinically healthy (Table 3).

After reading of all the X rays films, yet another child had to be excluded because of multiple exostoses.

Three were excluded because they were not yet 7 years of age. This leaves 1009 children whose age distribution is shown in Table 4.

Chapter 3

Material

The study comprised a total of 1025 children, 959 in the age range 7–17 years from a council school (Nyboder skole) and 66 aged 17–18 years from the neighbouring grammar schools Niels Steensen Østre Borgerdyd and Sortedam, all in Copenhagen

The children from Nyboder were chosen because they were believed to represent rather different socio-economic strata of the Copenhagen population This proved to be so In respect to parents occupation as well as income all groups are represented The distribution in social groups in relation to this distribution for the whole of Copenhagen is apparent from the chapter on skeletal maturation in relation to social circumstances.

The grammar-school pupils were included in order to elucidate also the last stages in the maturation of the hand skeleton.

After perusal of the health cards for

Chapter 4

Method

The *examination of the boys* consisted in

1. X ray of the right hand
2. Measurement of standing height.
3. Measurement of size of testes.
4. Measurement of length of penis.
5. Assessment of pubic hair mous-tache, and voice

The *examination of the girls* consisted in

1. X-ray of the right hand.
2. Measurement of standing height
3. History taking concerning time of menarche
4. Assessment of breast development.
5. Assessment of pubic hair

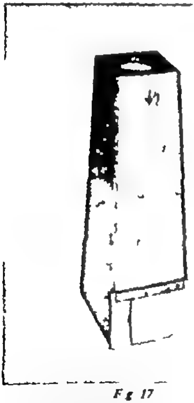

Fig 17

The box used in X-raying the hand and wrist. The box is lined with lead. The X-ray tube was placed in the circular hol in the top of the box and the X-ray film on its floor

The *examination by X ray* was done in the Dental Clinic of the Nyboder School using a dental tube.

For this purpose a wooden box was designed Its floor sides, and ceiling were lined with lead (Fig 17)

The floor measured 19×25 cm to accommodate an 18×24 cm film (the *film size most often used in X raying* hands) The top was provided with a circular hole *to* admit the X ray tube *during the exposure In this way* the focus-film distance was constant 7? cm

The figure shows, at the bottom of the box on one side an opening to admit the film and the hand to be X-rayed The right hand is placed with extended fingers and the volar side of the hand and wrist on the middle of the film (Fig 18)

The use of this box involves two advantages

1. Radiation is restricted to the child's right hand.
2. The focus-film distance is constant. The exposure factors were 60 kV 16 mA, and 0.8–1 2 sec. Only Sino films were used. The films were heavily exposed and read in strong light.

5 boys had to be X-rayed again, because the first films had not included the entire distal epiphysis of the radius.

Height was measured at full stretch, applying gentle traction under the mastoid processes and telling the child to stretch up as much as possible (technique of Tanner) The measurements were made by the school nurse after instruction and subsequent checking

Height was recorded as the nearest whole cm as done by Dossing (1950) One measurement was made on each pupil.

Fig 18.

Positioning of boy for an X-ray of the hand and wrist. At the bottom of the box, on one side, an opening to admit the hand. The fingers are extended and the volar side of the hand and wrist rests on the middle of the film

Boys

Testes. By a slide caliper 3 polar measurements were obtained on both sides. The tables state the mean measurement in mm. There is a linear correlation between the polar measurement and the volume of the testis (Quaade 1955)

Penis The length of the penis was measured by supporting the slide caliper against the symphysis at the base of the penis and placing the penis along the scale of the slide caliper The measurement was read in mm at the tip of the penis regardless of the appearance of the prepuce. The mean of 3 measurements was recorded.

Pubic hair was estimated by a method described by Greulich et al. (1942) and used by Quaade (1955) in a Danish material. The development of the pubic hair was divided into 4 stages

1. Vellus, the infantile stage.
2. Scattered pigmented, straight hair
3. Curled pigmented hair at the base of the penis.
4. Spread of curled pigmented hair to a larger area, in some cases along the linea alba and the medial sides of the thighs.

It was noted whether a *moustache*

Procedure of Determining Skeletal Age

The skeletal age was assessed both by Greulich & Pyle's atlas and by the system of Tanner & Whitehouse. The assessment was done without the author knowing the chronological age of the child whose X-ray film was being read. The skeletal age was stated, as done by Greulich & Pyle, in the nearest whole or half year. The accuracy of this procedure will be discussed in Chapter 6.

By reading about 300 films of the hand skeleton of children of all ages, which had previously been read by an experienced radiologist using the Greulich & Pyle atlas, and comparing my results with his, I had attained considerable practice in the use of Greulich & Pyle's atlas.

Preliminary Result

To gain a preliminary impression of the skeletal age in relation to chronological age in this material the difference between skeletal age and chronological age was calculated for every 10th girl and boy. Assessed by the method of Greulich & Pyle, the skeletal age was about 5 months below the chronological age. Assessed by the system of Tanner & Whitehouse, the skeletal age deviated, for boys aged 7–15 years and for girls aged [illegible]–13 years, by only a few months from the chronological age, while for the ages above this there was a striking difference between skeletal and chronological age suggesting possible faults of the method or errors in assessing the skeletal age of the almost full-grown children.

As described in discussing the method of Tanner & Whitehouse, a bone must fulfill certain maturity criteria to be assessed as having attained a certain stage of maturation. For instance, the criterion for the navicular bone to have reached its final stage is "The gaps between the navicular bone and the greater and lesser multangulars, capitate, and lunate are reduced to their adult dimensions. There is virtual contact between the navicular and the lunate throughout the whole of their adjacent borders" If there is no virtual contact between the navicular and the lunate, the navicular has reached only stage 7 If the film is, say from a girl of 13 whose stage of skeletal maturation corresponds approximately to her chronological age, a difference from stage 7 to 8 for the navicular gives a difference in skeletal age of only a few months, but if the film is

i.e. pigmented hair was present laterally on the upper lip

Lastly it was estimated whether the *voice* had broken

Girls

The girls were asked whether the *menarche* had occurred and if so when

Breast development was assessed by a classification into 4 stages as described by Stratz and used by Quaade (1955)

1 The infantile stage in which the areola is flat, the nipple slightly prominent no glandular tissue.
2 Prominence of the areola and nipple, incipient development of glandular tissue.
3 Increased amount of glandular and fatty tissue. Areola and nipple still prominent, forming a separate mound above the level of the breast.
4 Breast fully developed. Areola on a level with the skin, nipple more or less prominent

Pubic hair was estimated by criteria corresponding to those used for the boys

1 Vellus, the infantile stage.
2. Scattered pigmented straight hair
3 Pigmented curled hair on the labia and mons pubis around the midline.
4 Fully developed pubic hair of a feminine distribution limited by a horizontal line superiorly

Chapter 5

Procedure of Determining Skeletal Age

The skeletal age was assessed both by Greulich & Pyle's atlas and by the system of Tanner & Whitehouse. The assessment was done without the author knowing the chronological age of the child whose X-ray film was being read. The skeletal age was stated as done by Greulich & Pyle, in the nearest whole or half year. The accuracy of this procedure will be discussed in Chapter 6.

By reading about 300 films of the hand skeleton of children of all ages, which had previously been read by an experienced radiologist using the Greulich & Pyle atlas, and comparing my results with his, I had attained considerable practice in the use of Greulich & Pyle's atlas.

Preliminary Result

To gain a preliminary impression of the skeletal age in relation to chronological age in this material, the difference between skeletal age and chronological age was calculated for every 10th girl and boy. Assessed by the method of Greulich & Pyle, the skeletal age was about 6 months below the chronological age. Assessed by the system of Tanner & Whitehouse, the skeletal age deviated for boys aged 7–15 years and for girls aged 7–13 years, by only a few months from the chronological age, while for the ages above this there was a striking difference between skeletal and chronological age, suggesting possible faults of the method or errors in assessing the skeletal age of the almost full-grown children.

As described in discussing the method of Tanner & Whitehouse, a bone must fulfill certain maturity criteria to be assessed as having attained a certain stage of maturation. For instance, the criterion for the navicular bone to have reached its final stage is "The gaps between the navicular bone and the greater and lesser multangulars, capitate, and lunate are reduced to their adult dimensions. There is virtual contact between the navicular and the lunate throughout the whole of their adjacent borders." If there is no virtual contact between the navicular and the lunate, the navicular has reached only stage 7. If the film is, say from a girl of 13 whose stage of skeletal maturation corresponds approximately to her chronological age, a difference from stage 7 to 8 for the navicular gives a difference in skeletal age of only a few months, but if the film is of an almost full-grown girl, the same

difference in the assessment of the navicular will give a difference of more than 2 years in the assessment of skeletal age. This is due to the fact that the rating scale for the carpal bones increases abruptly to the last stage from the last but one and that the rating scale for the entire hand increases very slowly in the older age groups.

At times, it may be difficult to decide whether the bone is to be rated as stage 7 or 8 when dealing with the greater multangular the lesser multangular the lunate, the hamate, and the triquetral If the triquetral is to be assessed as having reached stage 8 the following criterion has to be fulfilled "The distal portion has now broadened so that it is nearly or quite as wide as the proximal portion" or the bone has now its adult appearance, and there is frequently overlapping between the edges of the triquetral and the hamate In fact it is frequently impossible to decide with certainty whether the bone has reached stage 7 or 8 Normally the round bones are completing their maturation around puberty before the fusion of epiphyses with diaphyses occurs in the metacarpal and phalangeal bones.

Although I had tried to follow the instructions as accurately as possible, I got strikingly low skeletal ages for the older age groups.

Visiting the Institute of Child Health Department of Growth and Development" University of London I had the opportunity of discussing my results with J M Tanner and R. H. Whitehouse They pointed out that in addition to rating each bone separately it is important in the assessment, to view the hand as a whole, and when the process of epiphyseal closure in the fingers was under way it could be deduced that the development of the carpal bones had been completed, and these bones could therefore be rated as in an adult.

To ascertain whether my use of Tanner & Whitehouse's method was in other respects justified I estimated in blind experiments 119 films of children of all ages which had previously been assessed by Tanner and Whitehouse. The two assessments proved identical apart from the fact that consistently I estimated the skeletal age as being a month or two higher

After having received the named instruction in assessing the carpal bones, I repeated my assessment of the films of boys who were over 13 years of age and girls who were over 11 Thus, I felt that I had repeated the assessment of all films in which the carpal bones had reached stage 7 or 8

The first and second assessments by the Tanner & Whitehouse system will be called Tanner & Whitehouse I and II

Chapter 8

Result and Accuracy of Skeletal Age Assessment

Tables 5 and 6 give, for boys and girls respectively means (M) and standard deviations (SD) for the difference between the chronological ages and skeletal ages assessed by the Greulich & Pyle and the Tanner & Whitehouse methods. Two series are listed, I and II for skeletal ages assessed by the system of Tanner & Whitehouse. These skeletal ages are identical for the younger age groups, but from the age of 13 for the boys and 11 for the girls a new assessment was done, as already mentioned, i.e. series II. Furthermore, the tables give the difference in skeletal age when assessed according to Greulich & Pyle and according to Tanner & Whitehouse.

Skeletal age (SA) assessed by the method of Greulich & Pyle is seen to be on the whole lower than chronological age (CA) indicating that the children of the American material were mature earlier than those of the Danish material. This is quite likely according to what is apparent from the chapter on maturation in relation to social circumstances, as the children of the American study were from homes far above the average educational and economic level. The difference averages 3.9 and 5.2 months for boys and girls respectively

Assessment of the films by the method of Tanner & Whitehouse, i.e. Tanner & Whitehouse II which is supposed to be the more correct assessment, showed that skeletal ages for boys as well as for girls in this country are on an average 2.3 months above the chronological ages. As far as the oldest girls are concerned, however the skeletal ages, assessed by the method of Tanner & Whitehouse, were on the average lower than the chronological ages. The explanation is presumably that the upper limit of skeletal maturity which is fixed in Tanner & Whitehouse's system arbitrarily at 17 years, is low for the girls of the present material.

The difference between skeletal age and chronological age varied from age to age. The same finding has been made in other materials in which the skeletal age in different groups of children has been determined according to the atlas of Greulich & Pyle. This variation in the difference between skeletal age and chronological age may be due to a certain heterogeneity in the assessment, since the assessment is earlier at some ages than at others. Apart from this, it may be due to a difference between the materials upon which the systems for skeletal age estimation are based and the present material. In as-

difference in the assessment of the navicular will give a difference of more than 2 years in the assessment of skeletal age. This is due to the fact that the rating scale for the carpal bones increases abruptly to the last stage from the last but one and that the rating scale for the entire hand increases very slowly in the older age groups.

At times, it may be difficult to decide whether the bone is to be rated as stage 7 or 8 when dealing with the greater multangular the lesser multangular the lunate, the hamate, and the triquetral. If the triquetral is to be assessed as having reached stage 8 the following criterion has to be fulfilled 'The distal portion has now broadened, so that it is nearly or quite as wide as the proximal portion or the bone has now its adult appearance, and there is frequently overlapping between the edges of the triquetral and the hamate In fact it is frequently impossible to decide with certainty whether the bone has reached stage 7 or 8 Normally the round bones are completing their maturation around puberty before the fusion of epiphyses with diaphyses occurs in the metacarpal and phalangeal bones.

Although I had tried to follow the instructions as accurately as possible, I got strikingly low skeletal ages for the older age groups.

Visiting the Institute of Child Health Department of Growth and Development University of London, I had the opportunity of discussing my results with J M Tanner and R H Whitehouse. They pointed out that in addition to rating each bone separately it is important in the assessment to view the hand as a whole, and when the process of epiphyseal closure in the fingers was under way it could be deduced that the development of the carpal bones had been completed, and these bones could therefore be rated as in an adult.

To ascertain whether my use of Tanner & Whitehouse's method was in other respects justified I estimated in blind experiments 119 films of children of all ages which had previously been assessed by Tanner and Whitehouse. The two assessments proved identical apart from the fact that consistently I estimated the skeletal age as being a month or two higher

After having received the named instruction in assessing the carpal bones, I repeated my assessment of the films of boys who were over 13 years of age and girls who were over 11 Thus, I felt that I had repeated the assessment of all films in which the carpal bones had reached stage 7 or 8

The first and second assessments by the Tanner & Whitehouse system will be called Tanner & Whitehouse I and II

sessing the films in Greulich & Pyle's atlas by the method of Tanner & Whitehouse for the age from 7 years and upwards, I found, for boys as well as for girls, an average difference of 7.1 months. The difference varied from age to age. In the older ages it was slight and in the younger ages greater. This variation in the difference between skeletal age and chronological age makes the total SD given in the extreme right hand column of Tables 5 and 6 somewhat greater than the average SD for the individual age groups.

Standard Deviation of the Skeletal Age Assessment

The total standard deviation includes the biological variation as well as the error of measurement of the skeletal age assessment. As the biological variation is the same in the various methods of assessment, a difference in total standard deviations, when using the two different methods, must indicate a difference in the error of measurement. However the differences in the standard deviations when the films were assessed by the method of Tanner & Whitehouse and by that of Greulich & Pyle are so slight that one method cannot be said to be more accurate than the other. The total SD for boys by Greulich & Pyle's method is 12.5 months, by Tanner & Whitehouse's method I 13.0 and by Tanner & Whitehouse II 13.3 months. The total SD for the girls by Greulich & Pyle is 11.9 months, by Tanner & Whitehouse I 13.1 months, and by Tanner & Whitehouse II 11.5 months.

By direct comparison of the assessed skeletal ages by the methods of Greulich & Pyle and of Tanner & Whitehouse, it is possible to estimate the error of measurement, presupposing that the errors of measurement are equally great and also independent, i.e. that the two methods do not employ the same criteria. This presupposition is only partially fulfilled.

The difference between skeletal ages measured by Tanner & Whitehouse's and by Greulich & Pyle's methods averages 8.4 months for the boys and 7.7 months for the girls. The total SD is 8.9 months for boys as well as for girls. Accordingly the error of measurement of a single reading has a SD of $\frac{8.9}{\sqrt{2}}$ which gives 6.3 months.

For a fixed chronological age, the variance of skeletal age must be equal to the sum of the biological variance and the variance of the error of measurement. The SD of the error of measurement being 6.3 months, the variance is the square of this value, or 39 months, and the variance in skeletal age will then, when using the Greulich and Pyle method average 12.2^2 or 149 months for boys and girls. Accordingly the biological variance will be 149 − 39 = 110 months. Extraction of the square root of this value gives the biological SD 10.5 months.

Although these estimates carry a fairly marked uncertainty they probably represent the proportionate significance of the two factors. By the method of Greulich & Pyle the skeletal age is recorded, as mentioned above, in the nearest whole or half years. It may be calculated that the total variance

les 5 and 6 Differences between skeletal age and chronological age in assessing the X ray films by Greulich & Pyle's atlas and by Tanner & Whitehouse
m. Differences in skeletal age when the films were assessed by the methods of Greulich & Pyle and of Tanner & Whitehouse. Tanner & Whitehouse I an
II indicate the results of 2 different assessments. The results are tated as mean differences (M) and standard deviations (SD) both in months.

sessing the films in Greulich & Pyle's atlas by the method of Tanner & Whitehouse for the age from 7 years and upwards, I found, for boys as well as for girls, an average difference of 7.1 months. The difference varied from age to age. In the older ages it was slight and in the younger ages greater. This variation in the difference between skeletal age and chronological age makes the total SD given in the extreme right-hand column of Tables 5 and 6, somewhat greater than the average SD for the individual age groups.

Standard Deviation of the Skeletal Age Assessment

The total standard deviation includes the biological variation as well as the error of measurement of the skeletal age assessment. As the biological variation is the same in the various methods of assessment, a difference in total standard deviations, when using the two different methods, must indicate a difference in the error of measurement. However the differences in the standard deviations when the films were assessed by the method of Tanner & Whitehouse and by that of Greulich & Pyle are so slight that one method cannot be said to be more accurate than the other. The total SD for boys by Greulich & Pyle's method is 12.5 months, by Tanner & Whitehouse's method I 13.0 and by Tanner & Whitehouse II 13.3 months. The total SD for the girls by Greulich & Pyle is 11.[illegible] months, by Tanner & Whitehouse I 13.1 months and by Tanner & Whitehouse II 11.3 months.

By direct comparison of the assessed skeletal ages by the methods of Greulich & Pyle and of Tanner & White house, it is possible to estimate the error of measurement, presupposing that the errors of measurement are equally great and also independent, i.e. that the two methods do not employ the same criteria. This presupposition is only partially fulfilled.

The difference between skeletal ages measured by Tanner & Whitehouse's and by Greulich & Pyle's methods averages 8.4 months for the boys and 7.7 months for the girls. The total SD is 8.9 months for boys as well as for girls. Accordingly the error of measurement of a single reading has a SD of $\frac{8.9}{\sqrt{2}}$ which gives 6.3 months.

For a fixed chronological age, the variance of skeletal age must be equal to the sum of the biological variance and the variance of the error of measurement. The SD of the error of measurement being 6.3 months, the variance is the square of this value, or 39 months, and the variance in skeletal age will then when using the Greulich and Pyle method, average 12.2^2 or 149 months for boys and girls. Accordingly the biological variance will be 149 − 39 = 110 months. Extraction of the square root of this value gives the biological SD 10.5 months.

Although these estimates carry a fairly marked uncertainty they probably represent the proportionate significance of the two factors. By the method of Greulich & Pyle the skeletal age is recorded, as mentioned above, in the nearest whole or half years. It may be calculated that the total variance

thus will be increased by approx. 3 and 12 months respectively in other words, the total SD has been increased by 0 2 and 1 month respectively so that the rounding off influences the results but little.

Author s Variable Error

In order to estimate my variable errors in assessing the X ray films, i.e. to estimate the certainty with which I could reproduce my assessment, I re peated the assessment of the films for every 10th girl and boy by the Greu lich & Pyle as well as by the Tanner & Whitehouse system. This repetition of the assessments by both methods al tered the mean values by less than 1 month i.e. not significantly By the Greulich & Pyle method the SD of the difference between the repeated read ings proved to be about 4 months and by the Tanner & Whitehouse method about 2 months. The number of repeat readings was 101

Mainland (1954) has investigated the variable error by assessing different series of films by the Greulich & Pyle atlas. He found the SD of the differ ence between duplicate assessments to be less than 3 months in some experi ments and slightly more than 4 months in others. Greulich & Pyle (1959) state that the assessment of X ray films car ries subjective errors and that the cer tainty of the assessment is expressed by the ability of the examiner to reproduce his readings. Referring to Mainland s variable error expressed in standard deviations of 3–4 months they state that this error is possibly rather high as the examiner was inexperienced in reading films. Greulich & Pyle do not report any investigations of their own into errors of measurement

Acheson (1963) has also studied the certainty by which an individual ex aminer can reproduce his readings The mean values were not significantly altered, and the standard deviations of the difference between the 1st and 2nd reading were 4 5 and 6 months for 3 different examiners, i. e. higher than Mainland s results which were 3 and 4 months.

The Systematic Error

Acheson (1963) made 8 examiners, 6 of whom were experienced and 2 in experienced assess the films of the hand skeletons of 50 boys and 50 girls ac cording to the Greulich & Pyle atlas and calculated the average skeletal age for all 100 films assessed by each ex aminer This showed a 4 month dif ference in skeletal age in the results of those examiners who had assessed the highest and lowest skeletal age. The in experienced examiners obtained values between the extreme values. Mainland (1953) found a systematic error of 4–5 months.

Those examiners who seldom or never used interpolation between the films of Greulich & Pyle s atlas ob tained standard deviations which were no higher than those of the other ex aminers.

Todd found that examiners of wide ly different experience in reading films do so with an accuracy of 6 months or less.

Discussion of the Size of the Standard Deviation

Since the standard deviations in assessing the present material by the methods of Greulich & Pyle and of Tanner & Whitehouse averaged 12.2 and 12.4 months respectively and thus were of the same magnitude as found by previous authors, the error of measurement in the present assessment of skeletal age is of a magnitude similar to those of others. As already mentioned, Greulich & Pyle found that the standard deviation in assessing the skeletal age of children aged 7 years and more averaged 10.6 months, i.e. somewhat lower than in the present study. This may be due to the biological variation in the healthy and well-to-do Brush Foundation material being less than in the present material. Assessment of children from Boston many of whom were of a socially poorer stratum than the Brush Foundation children, revealed an average SD of 11.6 months (Greulich & Pyle 1959). As mentioned above, the standard deviations in the material assessed by Tanner & Whitehouse by their own method was 12–12.5 months.

Preferred Method for Assessment of Skeletal Age

In analysing the relationship between skeletal maturation and other maturational criteria, the author used the results obtained by assessing skeletal age by Greulich & Pyle's atlas, partly because this method can be learnt far more quickly than Tanner & Whitehouse's and partly because it proved to be equally accurate.

thus will be increased by approx. 3 and 12 months respectively in other words, the total SD has been increased by 0 2 and 1 month respectively so that the rounding off influences the results but little.

Author s Variable Error

In order to estimate my variable errors in assessing the X ray films, i e to estimate the certainty with which I could reproduce my assessment, I repeated the assessment of the films for every 10th girl and boy by the Greulich & Pyle as well as by the Tanner & Whitehouse system. This repetition of the assessments by both methods altered the mean values by less than 1 month i.e. not significantly By the Greulich & Pyle method the SD of the difference between the repeated readings proved to be about 4 months and by the Tanner & Whitehouse method about 2 months. The number of repeat readings was 101

Mainland (1954) has investigated the variable error by assessing different series of films by the Greulich & Pyle atlas. He found the SD of the difference between duplicate assessments to be less than 3 months in some experiments and slightly more than 4 months in others. Greulich & Pyle (1959) state that the assessment of X ray films carries subjective errors and that the certainty of the assessment is expressed by the ability of the examiner to reproduce his readings. Referring to Mainland s variable error expressed in standard deviations of 3–4 months, they state that this error is possibly rather high as the examiner was inexperienced in reading films. Greulich & Pyle do not report any investigations of their own into errors of measurement.

Acheson (1963) has also studied the certainty by which an individual examiner can reproduce his readings. The mean values were not significantly altered, and the standard deviations of the difference between the 1st and 2nd reading were 4 5 and 6 months for 3 different examiners, i. e. higher than Mainland s results which were 3 and 4 months.

The Systematic Error

Acheson (1963) made 8 examiners, 6 of whom were experienced and 2 inexperienced assess the films of the hand skeletons of 50 boys and 50 girls according to the Greulich & Pyle atlas and calculated the average skeletal age for all 100 films assessed by each examiner This showed a 4-month difference in skeletal age in the results of those examiners who had assessed the highest and lowest skeletal age. The inexperienced examiners obtained values between the extreme values. Mainland (1953) found a systematic error of 4–5 months.

Those examiners who seldom or never used interpolation between the films of Greulich & Pyle s atlas obtained standard deviations which were no higher than those of the other examiners.

Todd found that examiners of widely different experience in reading films do so with an accuracy of 6 months or less.

Discussion of the Size of the Standard Deviation

Since the standard deviations in assessing the present material by the methods of Greulich & Pyle and of Tanner & Whitehouse averaged 12.2 and 12.4 months respectively and thus were of the same magnitude as found by previous authors, the error of measurement in the present assessment of skeletal age is of a magnitude similar to those of others. As already mentioned, Greulich & Pyle found that the standard deviation in assessing the skeletal age of children aged 7 years and more averaged 10.6 months, i.e. somewhat lower than in the present study This may be due to the biological variation in the healthy and well to-do Brush Foundation material being less than in the present material. Assessment of children from Boston, many of whom were of a socially poorer stratum than the Brush Foundation children, revealed an average SD of 11 6 months (Greulich & Pyle 1959) As mentioned above, the standard deviations in the material assessed by Tanner & Whitehouse by their own method was 12–12.5 months.

Preferred Method for Assessment of Skeletal Age

In analysing the relationship between skeletal maturation and other maturational criteria, the author used the results obtained by assessing skeletal age by Greulich & Pyle's atlas, partly because this method can be learnt far more quickly than Tanner & Whitehouse's and partly because it proved to be equally accurate.

thus will be increased by approx. 3 and 12 months respectively in other words, the total SD has been increased by 0 2 and 1 month respectively so that the rounding off influences the results but little.

Author s Variable Error

In order to estimate my variable errors in assessing the X ray films, i.e. to estimate the certainty with which I could reproduce my assessment, I repeated the assessment of the films for every 10th girl and boy by the Greulich & Pyle as well as by the Tanner & Whitehouse system. This repetition of the assessments by both methods altered the mean values by less than 1 month i.e. not significantly By the Greulich & Pyle method the SD of the difference between the repeated readings proved to be about 4 months and by the Tanner & Whitehouse method about 2 months. Dearing's heights are shifted half a year in relation to the others, because the average heights in his study were calculated for whole completed years. The heights in the present material were calculated for whole completed years as well as for the nearest year.

Chapter 7

Height

Introduction

In Chapters 7–13 an attempt will be made to evaluate to what extent skeletal age is applicable as a standard of biological maturation by comparing it with other criteria of maturation, such as height, menarche, maturation of breasts and of pubic hair etc.

Evaluation of skeletal age as a standard of biological maturation was done by comparing the relation of the named criteria to skeletal age with the relation of the same criterion to chronological age. In practice, this was done by grouping the material by skeletal age as well as by chronological age and by investigating for each subgroup the change in the maturational degree of the various criteria when the skeletal age and chronological age respectively are increased by one year

The curves illustrating the relation of the various maturational criteria to chronological age represent maturation in so far as it may be assumed that the present material is a representative section of children in the Danish population The curves present a snapshot of the maturation as the study was cross-sectional.

Previous Studies of Height

Tables 7 and 8 give, for boys and girls respectively a number of height tables from Sweden, Norway and Denmark as well as the height tables from the Brush Foundation study

Broman, Dahlberg & Lichtenstein's tables, which comprise children and adolescents from 1 to 20 years of age, were worked out on the basis of cross-sectional studies of 8441 children from maternity departments, day nurseries, nursery and other schools in Stockholm Malmö and Östergotland from the period 1938–1939 Tables 7 and 8 give only the results for the ages after 7 years, as the youngest children of the present study were 7 Broman, Dahlberg & Lichtenstein's tables are often used in Denmark.

Sundal (1957) analysed the height of 17 795 boys and girls in Bergen, Norway His material comprised measurements of the length of all newborn infants in Bergen in 1955 height measurements from the health centre of the Bergen Children's Hospital during the period 1952–1955 and height measurements done in March 1956 on 12 684 boys and girls aged 7–16 years in the Bergen schools.

In Norway the height and weight of Oslo school children aged 7–14 years has been recorded since 1920 in March of every year Every 5th

Chapter 7

Height

Introduction

In Chapters 7–13 an attempt will be made to evaluate to what extent skeletal age is applicable as a standard of biological maturation by comparing it with other criteria of maturation such as height, menarche, maturation of breasts and of pubic hair etc.

Evaluation of skeletal age as a standard of biological maturation was done by comparing the relation of the named criteria to skeletal age with the relation of the same criterion to chronological age. In practice, this was done by grouping the material by skeletal age as well as by chronological age and by investigating for each subgroup the change in the maturational degree of the various criteria when the skeletal age and chronological age respectively are increased by one year

The curves illustrating the relation of the various maturational criteria to chronological age represent maturation in so far as it may be assumed that the present material is a representative section of children in the Danish population The curves present a snapshot of the maturation, as the study was cross-sectional

Previous Studies of Height

Tables 7 and 8 give for boys and girls respectively a number of height tables from Sweden Norway and Denmark as well as the height tables from the Brush Foundation study

Broman Dahlberg & Lichtenstein's tables, which comprise children and adolescents from 1 to 20 years of age, were worked out on the basis of cross-sectional studies of 8441 children from maternity departments, day nurseries, nursery and other schools in Stockholm Malmö and Östergötland from the period 1938–1939 Tables 7 and 8 give only the results for the ages after 7 years, as the youngest children of the present study were 7 Broman Dahlberg & Lichtenstein's tables are often used in Denmark.

Sundal (1957) analysed the height of 17 795 boys and girls in Bergen Norway His material comprised measurements of the length of all newborn infants in Bergen in 1955 height measurements from the health centre of the Bergen Children's Hospital during the period 1952–1955 and height measurements done in March 1956 on 12 684 boys and girls aged 7–16 years in the Bergen schools.

In Norway the height and weight of Oslo school children aged 7–14 years has been recorded since 1920 in March of every year Every 5th

year the average height for each age has been calculated (Tables 9 and 10) From 1939 moreover the height of children from grammar schools has been recorded, so that from 1960 the tables contain height measurements for children aged 7–18 years. Almost 60,000 children have been measured. Through this period height has shown an increasing trend. However analysis of the values for 1955 showed that the increase in height had been considerably reduced, so that presumably the maximum had been reached. Bakwin & McLaughlin (1964) also found the increase in height to be decelerating, boys entering Harvard from municipal schools being 3.5 cm taller than 25 years ago, while the average height for boys entering Harvard from private schools had not altered during this period. Furthermore, pupils who came to Harvard from municipal schools in the years 1958–59 were of the same average height as the boys from private schools.

Densing's heights are shifted half line in relation to the others, because the average heights in his study were calculated for whole completed years. The heights [illegible] the present material were [illegible]alculated for whole completed years as well as for the nearest year

from 126 to 162, corresponding to an average annual height increment of about 5 cm.

The curve representing the boys growth in height runs a somewhat steeper course in the age group 12–15 years, indicating the faster growth during these years (the adolescent growth spurt) The girls curve is more even, presumably because the girls growth spurt is not as pronounced as the boys

If the Swedish, Norwegian, and American height tables are plotted graphically the curves are very reminiscent of Figs. 19 and 20. Their course is fairly parallel, but they are shifted a few cm from each other Figs. 21 and 22 illustrate the height curves for boys and girls of the Brush Foundation study of the present material, and of Broman, Dahlberg & Lichtenstein s material.

A calculation, for each age group, of the difference in height between the Brush Foundation material and the others shows that the children of the Brush Foundation material are tallest.

In the present material the boys were an average of 2.2 cm shorter and the girls an average of 2.8 cm shorter than the children of the American series. This corresponds to about [illegible] months of "height age" the mean annual

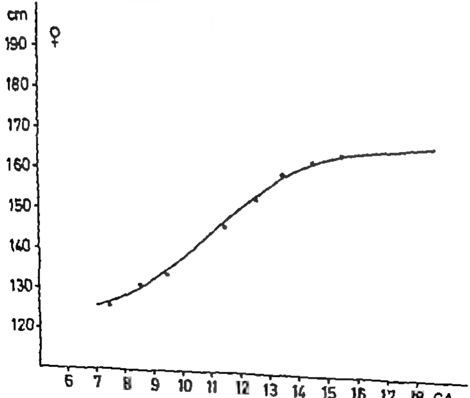

Fig 20

Height in relation to chronological age for the

The most recent analysis on the height of Danish children was performed by Døssing in 1950. From municipal primary schools and municipal grammar schools in Copenhagen he collected and analysed 17 439 height measurements from the health cards of the school health service from the 1930'ies and early forties. For each child included in the study there is a series of at least 6 measurements obtained at 1 year intervals.

Result of Height Analysis in the Present Study

Figs. 19 and 20 as well as Tables 11 and 12 present the variation in heights with chronological age for boys and girls of the present material. The curves afford an estimate of the average growth in height which will be found if a group of boys and girls born at the same time are followed by regular height measurements. As far as the boys are concerned the average height increases from 7 to 17 years of age from 127 to 179 cm i.e. by 52 cm corresponding to the average annual height increment of about 5 cm.

As far as the girls are concerned, height growth seems to decrease at the age of 14. The average height increases from 7 to 14 years of age by 36 cm,

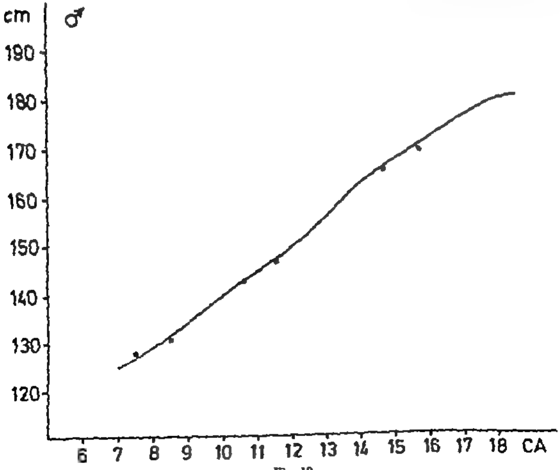

Fig. 19

Height in relation to chronological age for the boys of the present material.

from 126 to 162, corresponding to an average annual height increment of about 5 cm.

The curve representing the boys' growth in height runs a somewhat steeper course in the age group 12–15 years, indicating the faster growth during these years (the adolescent growth spurt). The girls' curve is more even, presumably because the girls' growth spurt is not as pronounced as the boys'.

If the Swedish, Norwegian, and American height tables are plotted graphically the curves are very reminiscent of Figs. 19 and 20. Their course is fairly parallel, but they are shifted a few cm from each other. Figs. 21 and 22 illustrate the height curves for boys and girls of the Brush Foundation study of the present material, and of Broman, Dahlberg & Lichtenstein's material.

A calculation, for each age group of the difference in height between the Brush Foundation material and the others shows that the children of the Brush Foundation material are tallest.

In the present material the boys were an average of 2.2 cm shorter and the girls an average of 2.8 cm shorter than the children of the American series. This corresponds to about [illegible] months of "height age" the mean annual

height increment being approx. 5 cm. It was expected that the Danish children would be a few cm shorter than the children of the American series, as the assessment of their skeletal age showed that the boys as well as the girls were retarded by about 6 months in relation to the children of the Brush Foundation study. The difference in height gain is most marked during the years of the growth spurt, less marked for the more advanced ages. The boys of Dossing's material were an average of 4.0 cm shorter and the girls an average of 3.3 cm shorter than those of the present material. The standard deviations are of almost the same size in all materials.

Table 13 gives, for boys and girls, the mean height difference between the Brush Foundation material and the named Scandinavian materials.

have not yet entered the adolescent growth spurt. These factors perhaps indicate that the value involves errors. Therefore, this age group should be left out in comparisons with other height tables. If the 11–17 year-old boys are compared with the corresponding age groups in the Brush Foundation material, the Swedish and American boys are seen to be of approximately the same height.

Falkner's height tables, worked out on the basis of 12 American height tables, show lower values than the Brush Foundation material. One of the 12 tables was set up by Meredith on the basis of investigations in the Iowa Child Welfare Research Station, the State University of Iowa 1930–1946. This set of tables is used in Nelson's Textbook of Pediatrics (1964). In the age range 7–17 years the boys of Meredith's material are an average of 1.7 cm and the girls an average of 2.6 cm shorter than the children of the Brush Foundation material.

Comparison of these height tables shows that the adolescent growth spurt is taking place ever earlier and that children in Scandinavia have not until recently approached the heights which had been attained by the children of the Brush Foundation material about 25 years ago.

Height in Relation to Skeletal Age

The curves in Figs. 23 and 24 illustrate height in relation to skeletal age for boys and girls.

The boys' curve runs a steeper course from skeletal age $11^{1}/_{2}$–15 years during which period the height gain is 8 cm per skeletal year. For the girls the curve is more even. Longitudinal studies have revealed that in boys the growth spurt occurs on the average from $12^{1}/_{2}$–15 years of age (chronological age). During this period they gain an average of 20 cm. In girls the growth spurt generally occurs 2 years earlier and is less marked than in the boys (Tanner). Although the present study is cross-sectional, it proved possible to visualize the adolescent growth spurt by relating height to skeletal age.

It may be noted that in Tables 11 and 12, giving the variation in heights with CA and SA respectively, chronological age is given in whole, completed years, (i.e. from one birthday to the next, 7 years meaning from the 7th until the 8th birthday) while skeletal ages indicate the nearest whole year.

The material was divided into half year groups: 7–$7^{1}/_{2}$ years, $7^{1}/_{2}$–8 years, etc., so that both whole, completed years and nearest whole years could be used to express chronological age. The tables most often state whole completed years for the following reasons. The material comprises children from municipal schools in Copenhagen.

Table 13

Average number of cm by which the children of the Brush Foundation material exceed various Scandinavian materials in height.

	Boys	Girls
Oslo *1960*	0.8 cm	1.6 cm
Denmark *1964*	2.2 –	2.8 –
Bergen 1956	2.7 –	3.6 –
Sweden *1938–1939*	2.6 –	3.3 –

from Stockholm is compared with the results of the present height analysis, it will be seen that boys and girls from grammar schools in the age range 7–17 years were then an average of 11 and 8 cm shorter.

The most recent Swedish height study is Abrahamson & Ernest's from 1954, but they studied only boys and only in the age range 10–18 years. The investigation was performed in 1950 on 871 boys in a Stockholm school. The result is shown in Table 14. A difference of only 1.2 cm between the 10-year-olds and 11-year-olds may seem surprising. Another striking factor is the high standard deviation for the 10-year-old boys who

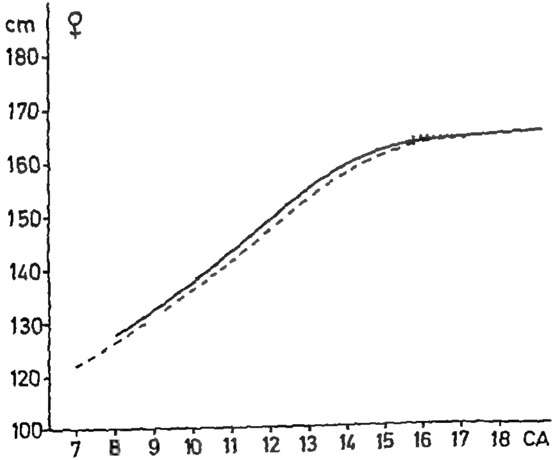

Fig. 2

have not yet entered the adolescent growth spurt. These factors perhaps indicate that the value involves errors. Therefore this age group should be left out in comparisons with other height tables. If the 11–17 year-old boys are compared with the corresponding age groups in the Brush Foundation material, the Swedish and American boys are seen to be of approximately the same height.

Falkner's height tables, worked out on the basis of 12 American height tables, show lower values than the Brush Foundation material. One of the 12 tables was set up by Meredith on the basis of investigations in the Iowa Child Welfare Research Station, the State University of Iowa 1930–1946. This set of tables is used in Nelson's Textbook of Pediatrics (1964). In the age range 7–17 years the boys of Meredith's material are an average of 1.7 cm and the girls an average of 2.6 cm shorter than the children of the Brush Foundation material.

Comparison of these height tables show that the adolescent growth spurt is taking place ever earlier and that children in Scandinavia have not until recently approached the heights which had been attained by the children of the Brush Foundation material about 25 years ago.

Height in Relation to Skeletal Age

The curves in Figs. 23 and 24 illustrate height in relation to skeletal age for boys and girls.

The boys' curve runs a steeper course from skeletal age 11 1/2–15 years during which period the height gain is 8 cm per skeletal year. For the girls the curve is more even. Longitudinal studies have revealed that in boys the growth spurt occurs on the average from 12 1/2–15 years of age (chronological age). During this period they gain an average of 20 cm. In girls the growth spurt generally occurs 2 years earlier and is less marked than in the boys (Tanner). Although the present study is cross-sectional, it proved possible to visualize the adolescent growth spurt by relating height to skeletal age.

It may be noted that in Tables 11 and 12, giving the variation in heights with CA and SA respectively, chronological age is given in whole, completed years, (i.e. from one birthday to the next, 7 years meaning from the 7th until the 8th birthday), while skeletal ages indicate the nearest whole year.

The material was divided into half year groups: 7–7 1/2 years, 7 1/2–8 years, etc., so that both whole, completed years and nearest whole years could be used to express chronological age. The tables most often state whole completed years for the following reasons. The material comprises children from municipal schools in Copenhagen.

At present children cannot enter school until after their 7th birthday However the material included 3 children who had nevertheless started before their 7th birthday but these 3 children were left out of the analysis. In order not to have to exclude also all children aged 7–7 ½ years it seemed advisable to use whole completed years. Where it was necessary in order to compare with materials in which the chronological age is given in nearest whole years, this grouping was also used for the present material (Tables 7 and 8) The grouping by whole completed years is advantageous, as the shift of ½ year between the chronological age and skeletal age fits the fact that the present children were retarded by about 6 *months* in relation to the American children. Therefore boys of a chronological age of say 10 but not yet 11 years measure 142 cm and so do boys whose skeletal age is 10 years.

The standard deviations in Tables 11 and 12 indicate how much the *height* varies *for* a given *chronological* age and a given skeletal age. These tables also give the standard deviation which appears if the chronological age as well as the skeletal age are kept constant On the average, the SD is 5 4 cm for boys as well as for girls.

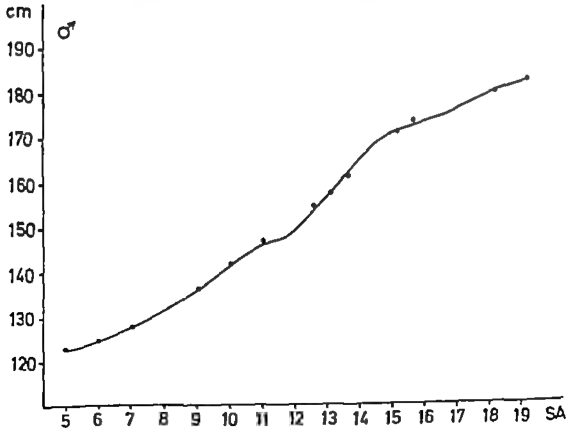

Fig 3
Height in relation to skeletal age for the boys of the present material.

The calculation was performed for those sub-groups which are obtained *when the material is grouped simultaneously into chronological six-month* groups and by skeletal age.

For the younger age groups the standard deviation is somewhat less pronounced than for the age groups which are in the *growth spurt*. The *average standard deviation corresponds* approximately to the variation in height found in adults. Broman, Dahlberg & Lichtenstein found, among men aged 20, a SD of 6.0 and for women 5.1 cm. These values are comparable with the 5.4 *cm*, since it may be assumed, *roughly* that the 20-year-old persons have reached skeletal maturity so that their SA is constant. This SD of 5.4 cm then is mainly due to an individual *variation independent* of age.

With a constant *SA* and a *varying* CA, the mean *SD* is 5.7 for boys and 5.6 cm for girls. With a constant CA and a varying SA, the increase in SD will be 19 % and 11 % respectively *making* 6.8 *cm for* boys and 6.2 *cm* for girls. This increase is greatest in the intermediate ages when growth is also fastest.

With a constant SA as well as CA, both boys and *girls* showed a *SD* of 5.4 cm, and with a *constant SA* and varying *CA* the SD was 5.7 for boys

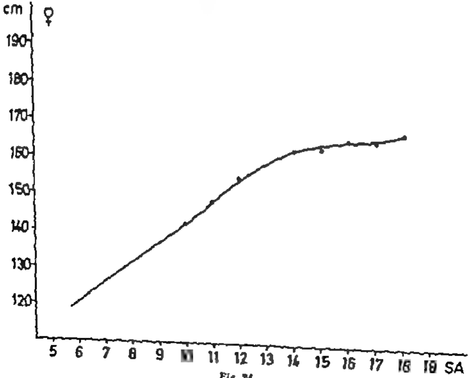

Fig 24

Height in relation to skeletal age for the girls of the present material.

At present children cannot enter school until after their 7th birthday However the material included 3 children who had nevertheless started before their 7th birthday but these 3 children were left out of the analysis. In order not to have to exclude also all children aged 7–7 ½ years, it seemed advisable to use whole completed years. Where it was necessary in order to compare with materials in which the chronological age is given in nearest whole years, this grouping was also used for the present material (Tables 7 and 8) The grouping by whole completed years is advantageous, as the shift of ½ year between the chronological age and skeletal age fits the fact that the present children were retarded by about 6 months in relation to the American children. Therefore boys of a chronological age of say 10 but not yet 11 years measure 142 cm and so do boys whose skeletal age is 10 years.

The standard deviations in Tables 11 and 12 indicate how much the height varies for a given chronological age and a given skeletal age. These tables also give the standard deviation which appears if the chronological age as well as the skeletal age are kept constant. On the average the SD is 5 4 cm for boys as well as for girls.

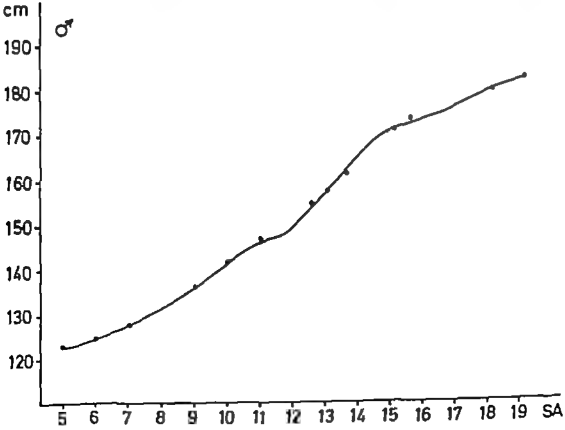

Fig 23

Height in relation to skeletal age for the boys of the present material

The calculation was performed for those sub-groups which are obtained when the material is grouped simultaneously into chronological six-month groups and by skeletal age.

For the younger age groups the standard deviation is somewhat less pronounced than for the age groups which are in the growth spurt. The average standard deviation corresponds approximately to the variation in height found in adults. Broman, Dahlberg & Lichtenstein found, among men aged 20, a SD of 6.0 and for women 5.1 cm. These values are comparable with the 5.4 cm, since it may be assumed, roughly that the 20-year-old persons have reached skeletal maturity so that their SA is constant. This SD of 5.4 cm then, is mainly due to an individual variation independent of age.

With a constant SA and a varying CA, the mean SD is 5.7 for boys and 5.6 cm for girls. With a constant CA and a varying SA, the increase in SD will be 19 % and 11 % respectively making 6.8 cm for boys and 6.2 cm for girls. This increase is greatest in the intermediate ages when growth is also fastest.

With a constant SA as well as CA, both boys and girls showed a SD of 5.4 cm, and with a constant SA and varying CA the SD was 5.7 for boys

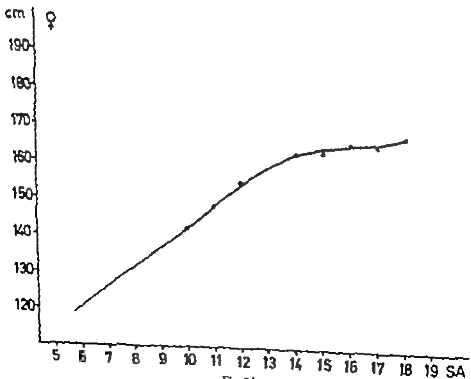

Fig. 24

Height in relation to skeletal age for the girls of the present material

At present children cannot enter school until after their 7th birthday How ever the material included 3 children who had nevertheless started before their 7th birthday but these 3 chil dren were left out of the analysis. In order not to have to exclude also all children aged 7–7 ½ years it seemed advisable to use whole com pleted years. Where it was necessary in order to compare with materials in which the chronological age is given in nearest whole years, this grouping was also used for the present material (Tables 7 and 8) The grouping by whole completed years is advanta geous as the shift of ½ year between the chronological age and skeletal age fits the fact that the present children were retarded by about 6 months in relation to the American children. Therefore, boys of a chronological age of say 10 but not yet 11 years meas ure 142 cm and so do boys whose skele tal age is 10 years.

The standard deviations in Tables 11 and 12 indicate how much the height varies for a given chronological age and a given skeletal age These tables also give the standard deviation which appears if the chronological age as well as the skeletal age are kept constant. On the average, the SD is 5 4 cm for boys as well as for girls.

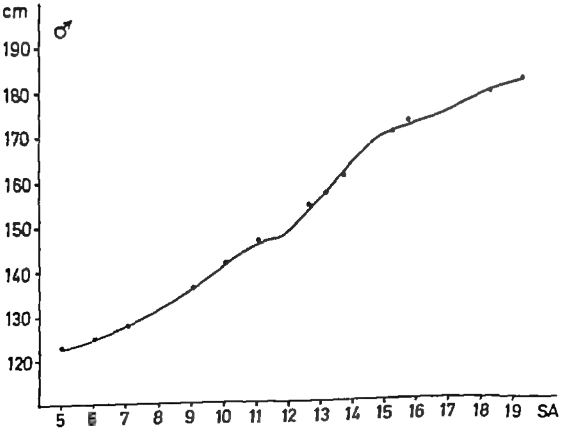

Fig 23
Height in relation to skeletal age for the boys of the present material

number n_1 and n_2 of observations in the two sub-groups.
When

$$w = \frac{n_1 \times n_2}{n_1 + n_2} \tag{1}$$

the average difference will be

$$\bar{d} = \frac{\Sigma\, w \times d}{\Sigma\, w} = \text{mean} \tag{2}$$

with the standard error

$$se < \bar{d} > = \frac{\sigma}{\sqrt{\Sigma\, w}} \tag{3}$$

were σ is the standard deviation of the heights in one sub-group.

It is apparent from Tables 15 and 16 that the difference in height, when skeletal age is shifted by 1 year and chronological age is constant, is 2.9 cm for boys aged 7–11 years, thereafter [illegible]1 cm up to the age of 14 and from 14 to 16 years of age 2.4 cm. With a constant skeletal age, the differences for a 1 year shift in chronological age are considerably lower. For the ages mentioned above the differences for boys are 2.3 cm, 2.1 cm and 1.8 cm.

For the girls the difference, with constant CA and a 1-year shift in SA, was 3.4 cm for the age 7–10 years, 3.8 for the age 10–13 years, and for the older ages 0.8 cm. With a constant SA and a 1 year shift in CA, the corresponding age groups showed differences of 3.0 cm, 2.0 cm, and 0.3 cm.

The individual differences carry a fairly marked uncertainty and therefore vary appreciably from age to age. As a whole, however they are positive both when SA and when CA are

Table 15

Change in height when the skeletal age or chronological age is shifted 1 year (the other parameter being kept constant)

Total		3.5±0.4			2.1±0.6

and 5 6 for girls, i.e. an increase of only 6 % and 4 %. This indicates that height depends more upon SA than upon CA.

Simmons (1944) relating the height measurements from the Brush Foundation material to chronological age as well as to skeletal age, found for most ages that the SD with a constant skeletal age was 20 % lower than with a constant chronological age. This corresponds approximately to the findings in the present material. For a few ages, however she found a reduction of 40 %. Bayley (1943) also found a closer relationship between height and skeletal age than between height and chronological age.

If instead of height itself the height could be expressed in per cent of adult height (Bayley 1943) the individual variation in height could have been almost approximately eliminated. This would also have given a greater difference between the standard deviations appearing when either the CA or the SA is constant

In the intermediate age groups the ratio between the standard deviations might be expected to be greater Bayley (1943) who demonstrated a high correlation between height and SA worked out tables, in collaboration with Pinneau (1952) showing the percentage of adult height to which various skeletal ages correspond On the basis of these tables, the adult height may be predicted when a child's skeletal age, height and chronological age are known. The accuracy expressed in SD is 2.5 cm if the skeletal age differs by 1 SD or less from the norm. The more advanced or retarded the skeletal maturation the less accurate the prediction. The accuracy decreases with decreasing age, the distance" from the 100 % which represents adult height increasing The tables are not applicable to children younger than 6 years.

The present results do not permit a definite evaluation of the dependence of growth upon skeletal age. Therefore an attempt was made to determine the alteration in average height when the SA is shifted 1 year while the CA is constant and to compare the change in height when the CA is shifted 1 year and the SA remains constant.

This method has the advantage of being applicable also to criteria of maturation such as the onset of menarche for which no continuous measurements are available.

The procedure was as follows The material was divided simultaneously by skeletal age, determined by the Greulich & Pyle method, and into chronological half year groups. For each of the resulting sub-groups the mean value for height was calculated In order to ascertain the importance of a shift in skeletal age from e.g 9 to 10 years, the author picked out those chronological ages for which observations were available for both skeletal ages, and calculated the difference between the mean values of heights for the two skeletal ages. It was found that these differences did not depend in any essential degree upon the chronological age for which they were calculated Therefore a common average was calculated. In calculating this average the weight w of the individual differences is given in relation to the

number n_1 and n_2 of observations in the two sub-groups.

When

$$w = \frac{n_1 \times n_2}{n_1 + n_2} \qquad (1)$$

the average difference will be

$$\bar{d} = \frac{\Sigma\, w \times d}{\Sigma\, w} = \text{mean} \qquad (2)$$

with the standard error

$$se < \bar{d} > = \frac{\sigma}{\sqrt{\Sigma\, w}} \qquad (3)$$

were σ = the standard deviation of the heights in one sub-group.

It is apparent from Tables 15 and 16 that the difference in height, when skeletal age is shifted by 1 year and chronological age is constant, is 2.9 cm for boys aged 7–11 years, there after 6.1 cm up to the age of 14 and from 14 to 16 years of age 2.4 cm. With a constant skeletal age, the differences for a 1 year shift in chronological age are considerably lower. For the ages mentioned above the differences for boys are 2.3 cm, 2.1 cm and 1.8 cm.

For the girls the difference, with constant CA and a 1 year shift in SA, was 3.4 cm for the age 7–10 years, 3.8 for the age 10–13 years, and for the older ages 0.8 cm. With a constant SA and a 1-year shift in CA, the corresponding age groups showed differences of 3.0 cm, 2.0 cm and 0.3 cm.

The individual differences carry a fairly marked uncertainty and therefore vary appreciably from age to age. As a whole, however they are positive, both when SA and when CA are

Table 15

and 5 6 for girls, i.e. an increase of only 6 % and 4 %. This indicates that height depends more upon SA than upon CA.

Simmons (1944) relating the height measurements from the Brush Foundation material to chronological age as well as to skeletal age, found for most ages that the SD with a constant skeletal age was 20 % lower than with a constant chronological age. This corresponds approximately to the findings in the present material. For a few ages, however she found a reduction of 40 %. Bayley (1943) also found a closer relationship between height and skeletal age than between height and chronological age.

If instead of height itself the height could be expressed in per cent of adult height (Bayley 1943) the individual variation in height could have been almost approximately eliminated. This would also have given a greater difference between the standard deviations appearing when either the CA or the SA is constant.

In the intermediate age groups the ratio between the standard deviations might be expected to be greater. Bayley (1943) who demonstrated a high correlation between height and SA, worked out tables, in collaboration with Pinneau (1952) showing the percentage of adult height to which various skeletal ages correspond. On the basis of these tables the adult height may be predicted when a child's skeletal age, height and chronological age are known. The accuracy expressed in SD is 2 5 cm, if the skeletal age *differs by 1 SD or less* from the norm. The more advanced or retarded the skeletal maturation, the less accurate the prediction. The accuracy decreases with decreasing age, the distance from the 100 % which represents adult height increasing. The *tables are not applicable to children* younger than 6 years.

The present results do not permit a definite evaluation of the dependence of growth upon skeletal age. Therefore an attempt was made to determine the alteration in average height when the SA is shifted 1 year while the CA is constant and to compare the change in height when the CA is shifted 1 year and the SA remains constant.

This method has the advantage of being applicable also to criteria of maturation such as the onset of menarche for which no continuous measurements are available.

The procedure was as follows. The material was divided simultaneously by skeletal age determined by the Greulich & Pyle method, and into chronological half year groups. For each of the resulting sub-groups the *mean value for height* was calculated. In order to ascertain the importance of a shift in skeletal age from e.g. 9 to 10 years, the author picked out those chronological ages for which observations were available for both skeletal ages, and calculated the difference between the mean values of heights for the two skeletal ages. It was found that these differences did not depend in any essential degree upon the chronological age for which they were calculated. Therefore a common average was calculated. In calculating this average the weight w of the individual differences is given in relation to the

skeletal as well as height age. Thereafter the terms which are specific to skeletal and height age respectively p and l depend upon biological factors, and and m indicate the error of measurement of the two determinations.

When SA varies and CA is constant, shift in SA of one unit will show an average distribution on the three quantities h, p and e in relation to their variances

$$\sigma_h^2,\ \sigma_p^2 \text{ and } \sigma_e^2.$$

In other words, when SA is changed by one unit, h and thus also HA will, on the average change

$$\frac{\sigma_h^2}{\sigma_h^2+\sigma_p^2+\sigma_e^2} \text{ units.}$$

With constant SA, the quantities on the right side in equation (5) will keep each other in equilibrium, so that when CA is changed by one unit, h+p+e must alter correspondingly in the opposite direction, and the change will be distributed on h, p, and in the same ratio as previously assuming that CA may be considered as being equally distributed within the age interval with which we are concerned.

The change in HA will correspond to the alteration in CA+h, which again corresponds to the alteration in p+e. Thus, HA will alter by

$$\frac{(\sigma_p^2+\quad^2)}{(\sigma_h^2+\sigma_p^2+\sigma_e^2)} \text{ units.}$$

Consequently when SA and CA respectively alter by one unit, the corresponding changes in HA will be rated as

$$q=\frac{\sigma_h^2}{\sigma_p^2+\sigma_e^2} \tag{7}$$

or since the intervals may be considered small, the changes in height measured in cm will have the same ratio.

I Chapter 6 the biological variation was estimated to be

$$\sigma_h^2+\sigma_p^2=110 \text{ months}$$

and the error of measurement

$$\sigma_e^2=39 \text{ months.}$$

Using (6)

$$\sigma_p^2=\frac{110-39\,q}{1+q}$$

When inserting the mean value q = 1 7

$$\sigma_p^2=13 \text{ months, or only } / \text{ of } \sigma\ ^2$$

Of course, these are uncertain estimates, but they do show that the dependence of height upon CA, with constant SA, is due mainly to difficulties in determining SA.

M. Nykahn.

Table 16

Change in height when the skeletal age or chronological age is shifted 1 year (the other parameter being kept constant)

Girls

Skeletal age increased			Chronological age increased		
Initial SA (years)	Difference cm		Initial CA (years)	Difference cm	
$5\ /_{12}$	5.5				
$6^{10}/$	3 6		7– 8	3 4	
$7^{10}/_{12}$	3 7	3 4±0.7	8– 9	1 0	3 0±1 0
$8^{10}/_{12}$	2.6		9–10	6 4	
10	4.3		10–11	0.5	
11	4 6	3.8±0 7	11–12	2.6	2.0±1 0
12	? 4		12–13	1 4	
13	1 3		13–14	−0.6	
14	0.9	0.8±0 7	14–15	−1.2	0.3±0.8
15	0.4		15–16	1 6	
16	−0 4		16–17	−0.4	
17	2.1				
Total		2 7±0 4			1 6±0 5

changed. *The means differ significantly from 0*

Here, and in the following the significance will be evaluated by the aid of

$$u = \frac{\text{difference}}{\text{standard error of difference}}$$

(When the CA is changed u takes the value 3 5*** for boys and 3 2** for girls)

The difference will also be significantly greater when the SA is *changed than when the CA is changed* For boys u = 2 3* and for girls 2 0* Calculation of a common u value for *the higher age groups gives u = 2.5**

The ratio of the two differences averages 1 7 for boys as well as girls.

A given skeletal age then affords a better estimate than a given chronological age of which percentage of its final height a child has attained

The reason why the correlation between height and skeletal maturation is not complete may be errors in determining skeletal age, but may also be that children who are skeletally retarded may have attained at a given skeletal age, a higher percentage of their adult height than advanced children of the same skeletal age (Bayley 1943)

Theoretically this may be set up as follows Assuming that skeletal ge as well as height age may be expressed as the sum of four independent quantities

$$SA = CA + h + p + e \qquad (5)$$

and

$$HA\ (\text{height age}) = CA + h + l + m \qquad (6)$$

The first term on the right indicates that the average course of the skeletal and height age will correspond t the chronological (CA) The following terms ndicate deviations from this average course First, common term h, comprising the factors which nfluence

skeletal as well as height age. Thereafter the terms which are specific to skeletal and height age respectively p and l depend upon biological factors, and and m indicate the error of measurement of the two determinations.

When SA varies and CA is constant, a shift in SA of one unit will show an average distribution on the three quantities h, p and in relation to their variances

$$\sigma_h^2, \sigma_p^2 \text{ and } \sigma^2$$

In other words, when SA is changed by one unit, h and thus also HA will, on the average change

$$\frac{\sigma_h^2}{\sigma_h^2 + {}_p^2 + \sigma_a^2} \text{ units.}$$

With constant SA, the quantities on the right side in equation (5) will keep each other in equilibrium, so that when CA is changed by one unit, h+p+a must alter correspondingly in the opposite direction, and the change will be distributed on h, p, and in the same ratio as previously assuming that CA may be considered as being equally distributed within the age interval with which we are concerned.

The change in HA will correspond to the alteration in CA+h, which again corresponds to the alteration in p+a. Thus HA will alter by

$$\frac{(\sigma_p^2 + {}^2)}{(\sigma_h^2 + \sigma_p^2 + \sigma^2)} \text{ units.}$$

Consequently when SA and CA respectively alter by one unit, the corresponding changes in HA will be rated as

$$q = \frac{\sigma_h^2}{\sigma_p^2 + \sigma_c^2} \qquad (7)$$

or since the intervals may be considered small, the changes in height measured in cm will fan the same ratio.

In Chapter 6 the biological variation was estimated to be

$$\sigma_h^2 + \sigma_p^2 = 110 \text{ months}$$

and the error of measurement

$$\sigma_c^2 = 39 \text{ months.}$$

Using (6)

$$\sigma_p^2 = \frac{110 - 39\,q}{1+q}$$

When inserting the mean value q = 1 7

$$\sigma_p^2 = 13 \text{ months, or only } 1/\ \text{ of } \sigma^2$$

Of course, these are uncertain estimates, but they do show that the dependence of height upon CA with constant SA, is due mainly to difficulties in determining SA.

M. Nyholm.

Chapter 8

Menarche

Previous Studies of Age at Menarche

The most important Danish study concerning the age at menarche is Bojlén Rasch & Weis Bentzon's (1954). In a material of 17,589 girls and young women aged 9 to 25 years attending schools, continuation courses, and evening schools in Copenhagen they collected data as to whether or not the pupil was menstruated and the time of menarche. This study was performed from 1948 to 1950.

The material was grouped by age into three month groups, but in the groups younger than 13 and older than 16 into six month groups. For each group the percentage of girls who were menstruated was calculated. The average age of menarche was found to be 13.8 years ± 1.0 SD. The same paper gives a list of other Danish menarche studies.

Author	Year	Number of patients	Age at menarche
Ravn	1850	3840	15.84
Hannover	1865	2129	16.91
Helms	1914	1000	ca. 15
Clausager Madsen & Ytting	1942	478	14.73
Gortz	1945	12..5	13
Auken	1951	314	14.2

Lundwall (1959) calculated on the basis of 2076 records from the Maternity Departments of the University Hospital Copenhagen for 1956 that the age at menarche was 14.3 years.

Evidently there is a tendency for the menarche to occur at an ever earlier age. However the values are not directly comparable, because the data on which they are based have been collected and analyzed in widely different ways.

Ravn (1850) collected his data mainly from the records of the University Maternity Department. Hannover's (1865) material comprised women of all ages admitted to Copenhagen hospitals during the period 1850–1865. Helms (1914) asked female patients aged 18–42 years admitted to a tuberculosis sanatorium about their age at the time of their first menstrual period.

Clausager Madsen & Ytting (1942) obtained their data from women who who had passed the menopause. Gortz (1945) studied the age at menarche in schoolgirls aged 10–15 by asking after which birthday the first menstrual period had occurred.

Some inaccuracy must be assumed to attach to the data concerning the time of menarche, as they depend upon

Tabl 17

Recent menarche studies based upon longitudinal investigations or upon the *status quo* method

Author	Year	Method and period of study	Number	Age at menarche
Simmons & Greulich Brush Foundation study U. S. A	1943	Longitudinal study 1931 1942	200	12 6
Reynolds & Wines, Fels Institute study U S A	1948	Longitudinal study 1938–1948	49	12.9
Bojlén, Rasch & Weis Bentzon, Denmark	1954	Status quo method 1948–1950	17,985	13 8
Wilson & Sutherland, South England	1961	Status quo method	2,180	13.2

girls by the same method as Schiøtz and Bojlén Rasch & Weis Bentzon found the age to be 13 65 years.

For comparison, Table 17 gives the age at menarche in other Scandinavian countries.

The age at menarche is higher in rural than in urban districts and higher in poor social strata (Ravn, Hannover Schiøtz, Simell 1952)

Lennér (1944) calculated that the age at menarche had fallen by 10 days for each of the past 50 years. According to Tanner the age at menarche has fallen by 4 months per decade. Lundwall made a similar finding in Denmark From 1860–1870 until 1956 the age at menarche for women admitted to the Maternity Departments of the University Hospital in Copenhagen had fallen from 17 0 to 14.3 years.

In analysing the age at menarche correct results may be obtained partly by the *status quo* method and partly by collecting data from longitudinal studies in which the exact time of the menarche has been recorded.

Som recent studies, carried out by these methods, are listed in Table 18

Previous Studies of the Relation Between Skeletal Age and Menarche

Only a few studies have dealt with the relation between skeletal age and the onset of the menarche. Simmons & Greulich (1943) investigated the time of menarche in 200 girls of the Brush Foundation study The average age at menarche proved to be 12 6 years or $12^7/_{12}$ years. The age varied from 122 to 183 months, i.e. by 61 months.

The average skeletal age, assessed by Todd's atlas, was 13 1 years at menarche. This difference between skeletal age and chronological age (13 1–12.6) of 6 months at menarche is due to the fact that the children upon whom Todd based his atlas were skeletally retarded by about 6 months compared with the Brush Foundation children

The skeletal age ranged from 144 to 174 months, i.e. it varied by 30 months or by only half the period found for the chronological age.

The standard deviation of CA at menarche was ± 12 75 months, while the standard deviation of SA was only ± 5.34 months.

In a longitudinal study of 36 girls Hansman & Maresh found the chronological age at menarche to be 13 09 years ± 1 15 SD while the skeletal age at menarche was 12 96 ± 0.58 SD Accordingly the SD of the SA at menarche is only half the SD of the CA at menarche.

Shuttleworth (1937) who gave particular attention to the relation of the menarche to the growth spurt, plotted groups of girls with different ages at menarche against their skeletal ages. It is apparent from his curves that the standard deviation of chronological age is twice the standard deviation of skeletal age at menarche

Age at Menarche in Present Material

girls by the same method as Schiøtz and Bojlén, Rasch & Weis Bentzon, found the age to be 13 65 years.

For comparison Table 17 gives the age at menarche in other Scandinavian countries.

The age at menarche is higher in rural than in urban districts and higher in poor social strata (Ravn Hannover Schiøtz, Simell 1952)

Lennér (1944) calculated that the age at menarche had fallen by 10 days for each of the past 50 years. According to Tanner the age at menarche has fallen by 4 months per decade. Lundwall made a similar finding in Denmark. From 1860–1870 until 1956 the age at menarche for women admitted to the Maternity Departments of the University Hospital in Copenhagen had fallen from 17 0 to 14.3 years.

In analysing the age at menarche correct results may be obtained partly by the *status quo* method and partly by collecting data from longitudinal studies in which the exact time of the menarche has been recorded

Som recent studies, carried out by these methods, are listed in Table 18

Previous Studies of the Relation Between Skeletal Age and Menarche

Only a few studies have dealt with the relation between skeletal age and the onset of the menarche. Simmons & Greulich (1943) investigated the time of menarche in 200 girls of the Brush Foundation study The average age at menarche proved to be 12 6 years or 12 7/12 years. The age varied from 122 to 183 months, i.e. by 61 months.

The average skeletal age assessed by Todd's atlas, was 13 1 years at menarche. This difference between skeletal age and chronological age (13 1–12.6) of 6 months at menarche is due to the fact that the children upon whom Todd based his atlas were skeletally retarded by about 6 months compared with the Brush Foundation children

The skeletal age ranged from 144 to 174 months, i.e. it varied by 30 months or by only half the period found for the chronological age.

The standard deviation of CA at menarche was ± 12 75 months, while the standard deviation of SA was only ± 5 34 months.

In a longitudinal study of 36 girls Hansman & Maresh found the chronological age at menarche to be 13 09 years ± 1 15 SD while the skeletal age at menarche was 12.96 ± 0 58 SD Accordingly the SD of the SA at menarche is only half the SD of the CA at menarche.

Shuttleworth (1937) who gave particular attention to the relation of the menarche to the growth spurt plotted groups of girls with different ages at menarche against their skeletal ages. It is apparent from his curves that the standard deviation of chronological age is twice the standard deviation of skeletal age at menarche

Age at Menarche in Present Material

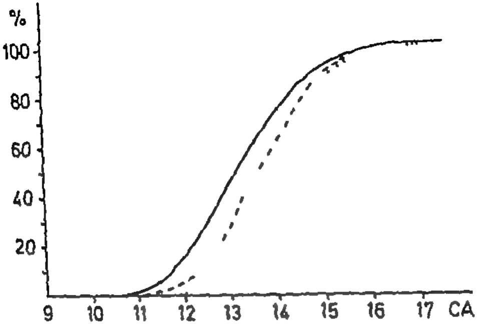

Fig 27

Percentage of girls who had reached menarche in relation to chronological age in

Boldsen, Rasch & Wels Benton material.
Quaade's material, and
— — the present material

1 year found in the earlier material.

The mean found in the present material is 8 months higher than that of the Brush Foundation material. This accords with the fact that in respect to height and skeletal maturation too the Danish material is about half a year retarded compared with the American material.

Age at Menarche in Relation to Skeletal Age in Present Material

Fig. 28 and Table 19 give the percentage of girls who had reached menarche in relation to skeletal age.

From the estimated cumulative distribution curve in Fig 28 the distribution curve was calculated and plotted as shown in Fig 29 The shape of this curve, like that in Fig. 26 is more illustrative, as the area within a given age interval represents the percentage of girls who attain menarche within this period. (Where the cumulative distribution curve ascends abruptly it is difficult to decide how far up the distribution curve will reach)

The curve shows that the earliest menarche occurs at a skeletal age of *10* years. At the outset the curve ascends slowly thereafter very abruptly in order suddenly to flatten out at skeletal age 13 ¹/₂ at which only 5 % had not started menstruating. Of

menarche at the different ages. The curve in Fig 25 has the same shape as those drawn on the basis of Bojlén Rasch & Weis Bentzon s and Quaade s menarche studies in Fig 27 The first onsets are at the age of 11 Initially the increase in per cent is slow there after faster around the age of 13 and at the age of 15 $^1/_2$ years 95 % of the girls had reached menarche. A distri bution like this is very like the normal cumulative distribution curve. In a large material Bojlén Rasch & Weis Bentzon demonstrated that this distri bution approximately fits the age at menarche. When the percentages were plotted on a probit diagram, the points in this material too were grouped along a straight line.

If the cumulative distribution curve is converted to a distribution curve, it proves to be the even symmetrical curve shown in Fig 26 Calculation of mean and standard deviation gives the age at menarche 13$^1/_4$ years ± 1$^1/_4$ year with the standard error se ± 0 24 year

The mean is about 6 months lower than in Bojlén, Rasch & Weis Bent zon s material which was collected about 15 years earlier A fall in the age at menarche in this order was to be expected since as previously stated the age at menarche in Europe has dropped during the past century by about 4 months per decade (Tanner) The mean differs significantly from that found by Bojlén Rasch & Weis Bentzon The standard deviation does not differ significantly from that of

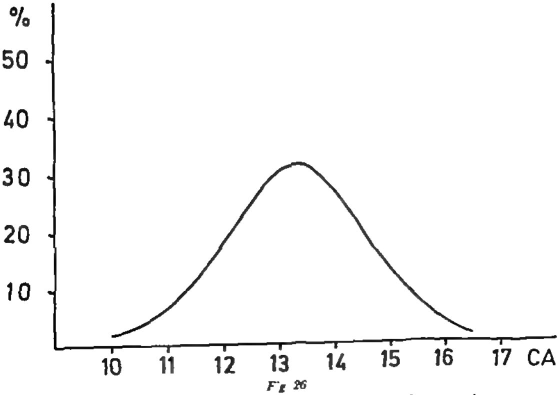

Fig 26

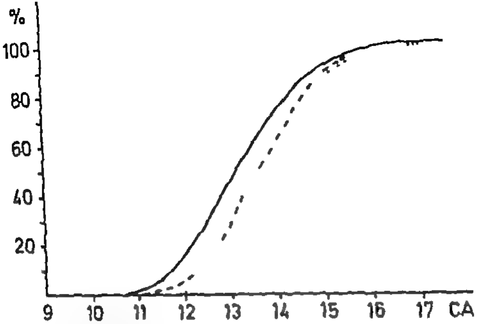

Fig. 27

Percentage of girls who had reached menarche in relation to chronological age in

Bojlén, Rasch & Weis Bentzon material.
Quaade material, and
— — — the present material

1 year found in the earlier material.

The mean found in the present material is 8 months higher than that of the Brush Foundation material. This accords with the fact that in respect to height and skeletal maturation too the Danish material is about half a year retarded compared with the American material.

Age at Menarche in Relation to Skeletal Age in Present Material

Fig. 28 and Table 19 give the percentage of girls who had reached menarche in relation to skeletal age.

From the estimated cumulative distribution curve in Fig. 28 the distribution curve was calculated and plotted as shown in Fig 29. The shape of this curve, like that in Fig 26 is more illustrative, as the area within a given age interval represents the percentage of girls who attain menarche within this period. (Where the cumulative distribution curve ascends abruptly it is difficult to decide how far up the distribution curve will reach.)

The curve shows that the earliest menarche occurs at a skeletal age of 10 years. At the outset the curve ascends slowly thereafter very abruptly in order suddenly to flatten out at skeletal age 13 $^1/_2$ at which only 5 % had not started menstruating. Of

course, this distribution cannot be approximated to a normal distribution.

This peculiar shape of the curve shows that the majority of the girls start menstruating within a much shorter time interval calculated in skeletal years than calculated in chronological years. 80 % of the girls reach their menarche in the course of $2^1/_4$ skeletal years, while 80 % reach their menarche in the course of about 4 calendar years.

This indicates a greater positive correlation between skeletal age and menarche than between chronological age and menarche. This aspect was investigated in further detail by comparing as for height how the percentages vary when CA and SA respectively is increased by 1 year However this comparison is more uncertain now that we are dealing with percentages and not with continuous measurements. But the method ought to be sufficient to estimate the ratio of the changes which take place when CA and SA respectively is shifted

The formulae for the weights (w) of the differences, the mean difference and standard error of the mean differences are the same as (1) (2) and (3) for the heights.

The standard deviation σ included in formula (3) is here

$$\sigma = \sqrt{h\ (100 - h)} \qquad (4)$$

where h is the frequency of the theoretical percentage of menarche which has occurred in the age group concerned

This value is not known, but in order not to underestimate σ and there

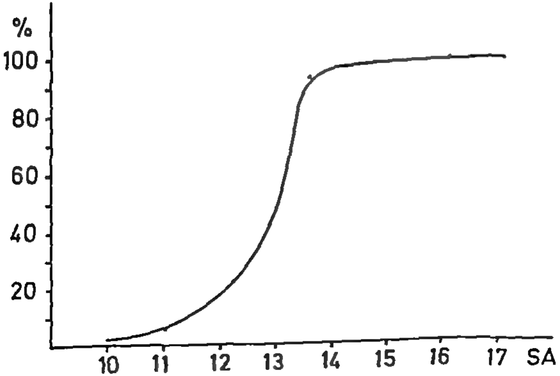

Fig 28

Percentage of girls who had reached menarche in relation to skeletal age (present material)

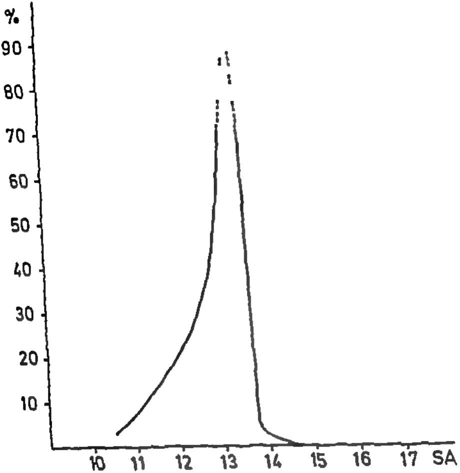

Fig 29

Distribution curve illustrating the percentage of girls reaching menarche in relation to skeletal age (present material)

by the uncertainty of the differences, h is fixed at 50, so that σ attains its maximum value $= 50$. In most cases, however the true value of σ cannot be much lower

In these calculations the author considered only those age groups where the greatest increase in menarche percentage from year to year occurs. For chronological age, whole-year age groups were used in order to procure sufficiently large numbers. The results are presented in Table 20

The change in the percentage of girls who had reached menarche is clearly greater when SA than when CA increases. The average values are 25.4 % $\pm$ 7.0 and 5.3 % $\pm$ 6.4 respectively The latter change is not significantly different from 0 ($u = 2.1$)

course, this distribution cannot be approximated to a normal distribution.

This peculiar shape of the curve shows that the majority of the girls start menstruating within a much shorter time interval calculated in skeletal years than calculated in chronological years. 80 % of the girls reach their menarche in the course of $2^1/_4$ skeletal years, while 80 % reach their menarche in the course of about 4 calendar years.

This indicates a greater positive correlation between skeletal age and menarche than between chronological age and menarche. This aspect was investigated in further detail by comparing, as for height, how the percentages vary when CA and SA respectively is increased by 1 year However this comparison is more uncertain now that we are dealing with percentages and not with continuous measurements. But the method ought to be sufficient to estimate the ratio of the changes which take place when CA and SA respectively is shifted.

The formulae for the weights (w) of the differences, the mean difference and standard error of the mean differences are the same as (1) (2), and (3) for the heights.

The standard deviation σ included in formula (3) is here

$$\sigma = \sqrt{h\ (100 - h)} \qquad (4)$$

where h is the frequency of the theoretical percentage of menarche which has occurred in the age group concerned

This value is not known, but in order not to underestimate σ and there

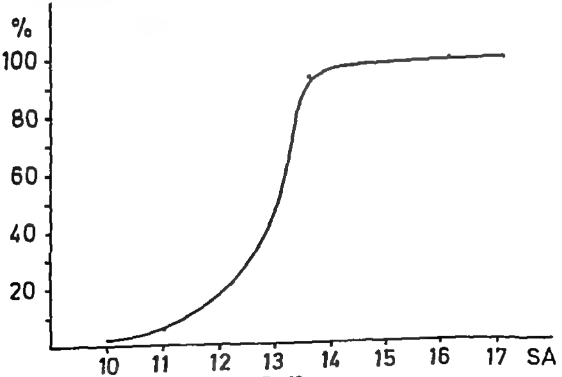

Fig 28

Percentage of girls who had reached menarche in relation to skeletal age (present material)

Present Study of Breast Maturation and Comparison with Previous Findings

Fig 30 illustrates *breast maturation in relation to chronological age* The curves were plotted on the basis of the values from Table 21 The curves, largely parallel, indicate the percentage of girls who have, at various chronological ages, attained stage II stage III and stage IV of breast maturation.

Breast maturation starts in a few per cent of the cases at the age of 8 Initially the curve ascends slowly then rather abruptly at the age of 10–11 years, and at 12 years of age breast maturation is in progress in 90 %

The development from stage II to IV occurs, on the average, from about $10^3/_4$ years to about $13^1/_2$ years of age, i.e. it takes about 3 years. In cases where breast maturation starts late, be cause of late puberty the development from stage II to stage IV takes about 4 years. Plotting of the points from

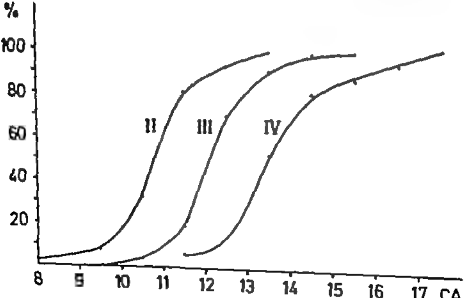

Fig 30

Percentage of girls who had attained stages II, III and IV of breast maturation in relation to chronological age (present material)

Table 20

Change in the percentage of girls who had reached menarche when the skeletal age or the chronological age is increased by 1 year Chronological age given in whole completed years.

Sk letal age held constant		Chronological ge held constant	
CA Increased	Difference in %	SA Increased	Difference in %
from 11 to 12 years	+ 2 1	from 11 to 12 years	+12.2
from 1 [illegible] 13 years	+16.4	from 12 to 13 years	+23 4
from 13 to 14 years	+ 0 7	from 13 to 14 years	+40 7
Total	+5 3 ± 6 4	Total	+25 4 ± 7 0

Conclusion

From this it is distinctly apparent that a change in skeletal age is of a decisive and far greater importance to the occurrence of menarche than is an increase in the chronological age, proving that skeletal maturation is better suited than chronological age as a measure of biological age. It may be assumed that the factors (probably hormonal) which determine the onset of menstruation are partially identical with those which regulate skeletal maturation.

Present Study of Breast Maturation and Comparison with Previous Findings

Fig 30 illustrates *breast maturation in relation to chronological age* The curves were plotted on the basis of the values from Table 21 The curves, largely parallel, indicate the percentage of girls who have, at various chronological ages, attained stage II stage III and stage IV of breast maturation.

Breast maturation starts in a few per cent of the cases at the age of 8 Initially the curve ascends slowly then rather abruptly at the age of 10–11 years, and at 12 years of age breast maturation is in progress in 90 %

The development from stage II to IV occurs, on the average from about 10³/₄ years to about 13¹/₂ years of age, i.e. it takes about 3 years. In cases where breast maturation starts late, because of late puberty the development from stage II to stage IV takes about 4 years. Plotting of the points from

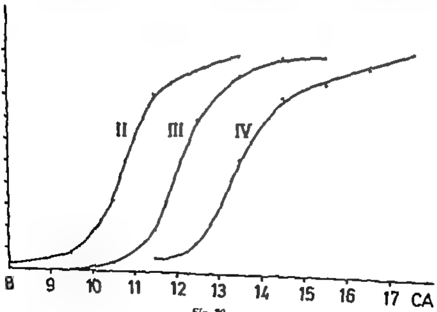

Fig 30

Percentage of girls who had attained stages II III and IV of breast maturation in relation to chronological age (present material)

Table 20

Change in the percentage of girls who had reached menarche when the skeletal age or the chronological age is increased by 1 year Chronological age given in whole completed years.

Skeletal age held constant		Chronological age held constant	
CA increased	Difference in %	SA increased	Difference in %
from 11 to 12 years	+ 2.1	from 11 to 12 years	+12.2
from 12 to 13 years	+16.4	from 12 to 13 years	+23.4
from 13 to 14 years	+ 0.7	from 13 to 14 years	+40.7
Total	+5.3 ± 6.4	Total	+23.4 ± 7.0

Conclusion

From this it is distinctly apparent that a change in skeletal age is of a decisive and far greater importance to the occurrence of menarche than is an increase in the chronological age, proving that skeletal maturation is better suited than chronological age as a measure of biological age. It may be assumed that the factors (probably hormonal) which determine the onset of menstruation are partially identical with those which regulate skeletal maturation.

Present Study of Breast Maturation and Comparison with Previous Findings

Fig 30 illustrates *breast maturation in relation to chronological age* The curves were plotted on the basis of the values from Table 21 The curves, largely parallel, indicate the percentage of girls who have, at various chronological ages, attained stage II, stage III and stage IV of breast maturation.

Breast maturation starts in a few per cent of the cases at the age of 8. Initially the curve ascends slowly then rather abruptly at the age of 10–11 years, and at 12 years of age breast maturation is in progress in 90 %

The development from stage II to IV occurs, on the average, from about $10^{7}/_{4}$ years to about $13^{1}/_{2}$ years of age i.e. it takes about 3 years. In cases where breast maturation starts late, because of late puberty the development from stage II to stage IV takes about 4 years. Plotting of the points from

Present study		Cross-sectional	532	1964	II 10.6±1.1	III 11.8	IV 13.5

Stages which, according to the description, correspond largely to each other are placed in the same column even though they have not always been given the same designation

curve II (Fig. 30) in a probit diagram gave an approximately straight line, i.e. the distribution was practically normal. Reading of this diagram gave a mean of 10.8 years, with a standard deviation of 1.1 year. The distribution curve is shown in Fig. 31.

For comparison, Table 22 gives the chronological ages at which the various stages of breast maturation had occur-

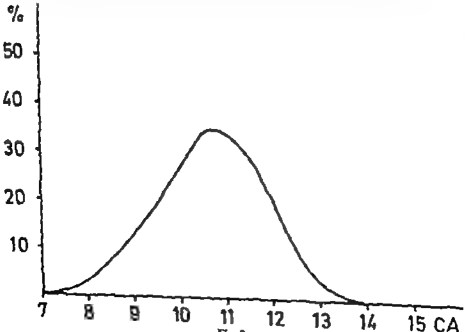

Fig. 3

Distribution curve showing the percentage of girls attaining stage II of breast maturation in relation to chronological age (present material)

red in previous studies. The stages which according to the description correspond largely to each other are placed below each other in the same columns, even though they have not always been given the same designation. In Quaade's (1955) as well as in the present study the method of Stratz was used in assessing the stage of breast maturation. The results are very similar. The standard deviations in Reynolds & Wines and in Hansman & Maresh investigations are identical with those in the present material. Breast maturation was not examined in the Brush Foundation study.

Plotting of the *breast maturation* found in the present study against *skeletal age* gives, as for the chronological ages, three almost parallel curves, representing breast maturation of stages II, III, and IV (Fig. 32). However, breast maturation usually starts at skeletal age 10.2 years, while for the chronological age it was 10.8 years. This is possibly because the children of the present material were retarded by about 6 months in relation to those of the Brush Foundation material. The development of the breast from stage II to IV takes an average of about 2 ½ years in terms of skeletal age.

Conversion of the curve representing stage II to a distribution curve shows an approximately normal distribution (Fig. 33). According to a probit diagram the mean was 10.2 and the standard deviation 1.1 year. In other words, the standard deviation is in the same range as for the chronological ages. Therefore, the correlation between

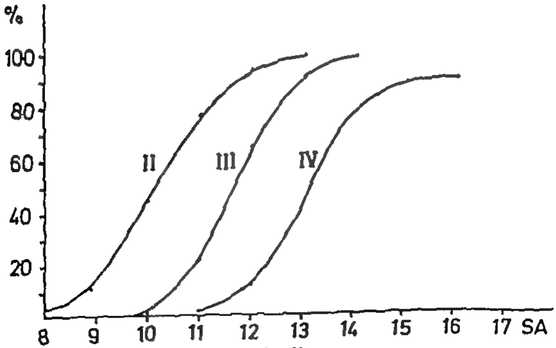

Fig. 32

Percentage of girls who had attained stages II, III and IV of breast maturation in relation to skeletal age (present material)

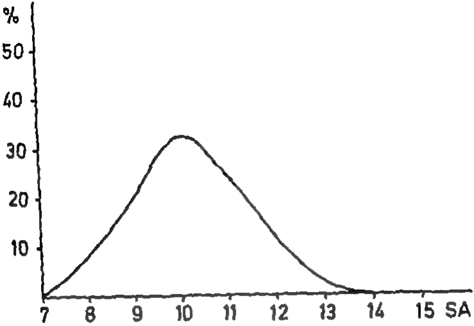

Fig 33

Distribution curv showing percentage of girls attaining stage II of breast maturation in relation to skeletal age (present material)

breast maturation and SA cannot be expected to be much higher than between breast maturation and CA. Hansman & Maresh, just like the present author found a standard deviation for stage II breast maturation of 1.1 year for CA as well as for SA.

To assess further the correlation between breast maturation and chronological age and between breast maturation and skeletal age, the author investigated, as for the menarche, the increase in the percentage of girls with incipient breast maturation (stage II)

Table 22.

Change in the percentage who attained stage IV of breast maturation among girls who were already in stage II, when either the CA or the SA is increased by 1 year

Skeletal age held constant		Chronological age held constant	
CA increased	Difference in %	SA increased	Difference in %
from 11 to 12 years	− 1.8	from 11 to 12 years	+10.9
from 12 to 13 years	−14.7	from 12 to [illegible] years	+34.9
from 13 to 14 years	+14.4	from 13 to 14 years	+19.1
from 14 to 15 years	− 3.9	from 14 to 15 years	+14.9
Total	+6.2 ± 5.6	Total	+20.8 ± 6.0

when either CA or SA is increased by 1 year Since the difference was not clear the author studied also the alteration in the percentage attaining breast maturation stage IV among girls already in stage II when either the CA or the SA was increased by 1 year

The result is shown in Table 23 The difference between the average increase in percentage, 20 8 ± 6 0 and 6 2 ± 5 6 indicates a greater dependence upon SA than upon CA, even though the difference cannot be said to be significant ($u = 1.5$)

Conclusion

Thus, for breast maturation too there is a tendency for a greater dependence upon SA than upon CA.

Present Studies of the Development of Pubic Hair and Comparison with Previous Findings

Girls

Tables 24 and Fig 34 illustrate the *development of pubic hair in relation to chronological age* The almost parallel curves indicate the percentage of girls who had attained, at the various ages, stages II III and IV of pubic hair development.

In a few per cent pubic hair appears at the age of 9 /₂. Initially the curve ascends slowly then rather abruptly at the age of 11–12 years. At the age of 13 the growth of pubic hair was in progress in 90 %

Development of pubic hair from *stage II to stage IV* took place, on the average, from age $11^3/_4$ years to $13^1/_2$, i.e. in the course of about 2 years. In cases where pubic hair appeared late, i.e. after the age of 13 the development from stage II to IV took about 4 years.

The distribution curve illustrating

stage II of pubic hair development shows an almost normal distribution. According to the probit diagram the mean was 11.6 years and the standard deviation 1.0 year.

Table 25 presents the chronological ages at which the various stages of pubic hair appeared in this and other materials. Chapter 2 described the methods by which the development of pubic hair has been assessed.

To be able to compare the various results, the stages which, according to the description, correspond approximately to each other, are tabulated in the same columns, even though they have not always been given the same designation. Quaade's (1955) study and the present one carried out by the same method, show similar results.

In Hansman & Maresh material pubic hair appeared about 1 year earlier than in the present material, but this does not warrant any conclusions, as the details of Hansman & Maresh material are not given. The girls of Reynolds & Wines' material, which was unselected, also showed earlier maturation in respect to pubic hair, but the difference is only about 6 months. The stated standard deviations are in the same range as in the present series.

Just as for chronological age, the *development of pubic hair* plotted against *skeletal age* gives almost parallel curves illustrating the percentages of children who have reached stages II, III, and IV (Fig. 35) at different skeletal ages. However, the appearance of pubic hair, measured in skeletal age, occurs on the average at 11 years of age, i.e. somewhat earlier than found for the chronological age. The development of pubic hair from stage II to stage IV takes on the average a little more than 2 years. The distribution curve illustrating stage II is approximately normal. According to the probit diagram M was 11.0 years and the standard deviation 1.0 year.

Since the standard deviation for the time of appearance of pubic hair is 1.0 years, in terms of CA as well as of SA, no difference could be expected in the correlation between appearance of pubic hair and CA and between appearance of pubic hair and SA.

Hansman & Maresh found that the

not significant. Thereafter the author investigated the increase in the percent age who attained pubic hair stage IV among girls who had already reached stage II when the CA and the SA respectively was increased by 1 year

The result is presented in Table 26 The significant difference between the average increase in the percentage + 1.35 when the SA is held constant and the CA is increased and + 16 28 when the CA is held constant and the SA is increased indicates a *closer correlation between pubic hair development and SA than between pubic hair development and CA* (u = 2 0*)

Boys

The development of pubic hair in relation to chronological age is illustrated in Table 27 and Fig 36

The 3 curves represent the percent age of boys who attain at the various ages, stages *II III* and *IV* of pubic hair development. The curves are very similar to those shown above for the girls.

In a very few per cent pubic hair starts appearing at the age of 10½. Initially the curve (stage II) ascends slowly thereafter rather abruptly around the age of 13 At the age of 14 the development of pubic hair is in progress in about 90 %

The development of pubic hair from stage II to IV takes place, on the average from age 12 8 to 15 2 years, i.e. in the course of a little more than 2 years.

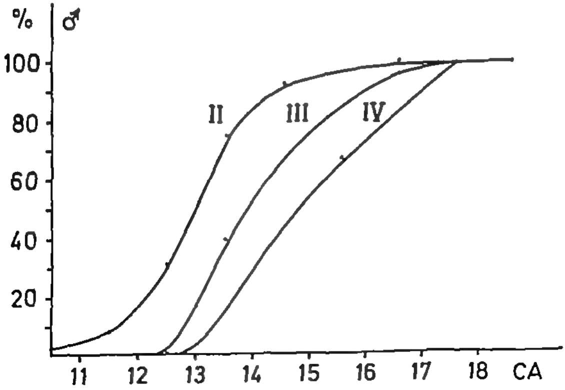

Fig 36

Percentage of boys who had attained stages II III and IV of pubic hair development in relation to chronological age (present material)

Table 28

Chronological age at which the various stages of pubic hair development occur

Boys.

Author	Year of publication	Longitudinal/cross-sectional study	No. of boys	Years of study	Stages		
Reynolds & Wines	1951	Longitudinal	59	1933–1946	II 12.2±1.1	IV 13.9	V 16.1
Hansman & Maresh	1961	Longitudinal	27	unknown	II 12.8±1.1		
Quaade	1955	Cross-sectional	489	1951	II $1^{00}/_{12}-13^{9}/_{12}$	III $13\ /_{12}-14^{2}/_{12}$	IV $14\ /_{12}-15^{2}/_{12}$
Present study		Cross-sectional	477	1964	II 12.8±1.1	III 13.8	IV 15.2

The stages which, according to the description, correspond to each other are tabulated in the same column, even though they have not always been given the same designation.

The distribution curve showing pubic hair stage II is approximately normal. According to the probit diagram, the mean was 12.8 years and the standard deviation 1.1 years. Thus, the mean is 1.2 years later than for the girls. Table 28 gives the ages at appearance of pubic hair in the studies of previous authors.

These ages at appearance of pubic

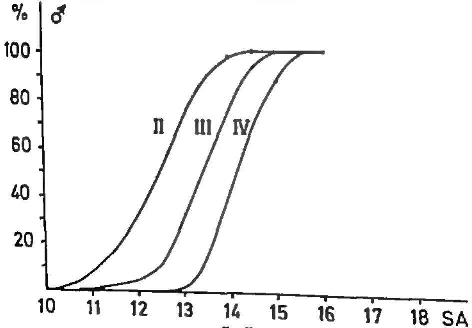

Fig. 37

Percentage of boys who had attained stages II, III, and IV of pubic hair development in relation to skeletal age (present material)

hair show fairly good conformity in the various studies.

Plotting the development of pubic hair against skeletal age again gives 3 almost parallel curves, representing *pubic hair in stages II III and IV* (Fig 37) The points on the stage II curve give, when inserted in a probit diagram, an almost rectilinear course, i e. an approximately normal distribution in which the mean was 12.4 years and the standard deviation 0 9 year Thus the mean with constant skeletal age is 0 4 year lower than with constant chronological age. This is presumably because the present children were retarded in relation to the children of the American material.

Since the difference between the standard deviation 1 1 years with constant chronological age and 0.9 year with constant skeletal age is not great no difference can be expected in the dependence of pubic hair upon CA and upon SA respectively

Hansman & Maresh found that the age of appearance of pubic hair had a standard deviation of 1 1 years for CA and of 0 8 year for SA.

In order to judge more closely the correlations between pubic hair development and chronological age as well as between pubic hair development and skeletal age, the author investigated as for the girls, the change in the percentage of boys who attained pubic hair stage IV among the boys who were already in stage II when the CA and the SA respectively was increased by 1 year

The result is shown in Table 29 The difference between the increased percentage, 5 0 when SA is held constant and the chronological age is increased and + 34 7 when CA is held constant and SA increased shows a *significantly higher correlation between pubic hair development and SA than between pubic hair development and CA* (u = 4 0***)

Table 29

Chapter 11

Studies of Testes Development

Previous Studies

Scammon (1930) in an autopsy study determined the weight of the testicles from 726 boys aged 0–20. He found the weight to be fairly constant up to the age of 11 whereupon it rose steeply up to age 20.

Only a few *in vivo* measurements have been reported. Reich (1924) measured the length and smallest width in 221 boys aged 0–15 years. The size

was found to be approximately unchanged up to 11 years of age, while from 11–16 the testes grew by 17–35 mm.

From-Hansen & With (1951) measured the testes of 251 boys under 20 years of age. The minimum values are shown in Table 30 which gives also the values found by Quaade (1955) in a study of 473 boys aged 7–15. In this latter material there was a considerable standard deviation within each age group. Means and standard deviations were unchanged up to 11–12 years, whereupon the means increased abruptly and the standard deviations too showed an appreciable increase.

Present Studies

Testicular size in relation to CA and SA is given in Table 31. The curve (Fig. 38) representing the *polar measurements of the testes in relation to chronological age* runs an almost horizontal course up to the age of 7–9 years. At 10 years *it starts ascending a little, from 11–14 years the rise is quite* abrupt, and then *the curve flattens* again. From 9–18 years of age the polar measurements of the testes increase by an average of 17–43 mm. The velocity curve (Fig. 39) shows that the peak increment occurs at the age 12 ½–13 years.

When the *testes measurements are*

from 15 to 16 years	−0.2		+4.5	
from 16 to 17 years	−0.7	+1.7 ± 0.9	+1.5	+1.4 ± 0.9
from 17 to 18 years	+3.2		−0.9	
	Total	+1.7 ± 0.5	Total	+1.9 ± 0.5

plotted against skeletal age it appears, in particular from the velocity curve (Fig 41) that the peak increment is greater than in Fig 39

From Fig 38 it was apparent that the testes increase in size by 25–40 mm in the course of 3 chronological years, while the same increment occurs in 2 ½ years when measured in skeletal years (Fig 40) This finding that the greater part of the increment measured in skeletal years, occurs within a shorter period than when measured in chronological years, gives rise to the presumption that testicular development is more closely related to SA than to CA.

To assess in more detail the relation between testicular growth and CA and between testicular growth and SA, the author studied the average increment when SA was held constant and CA increased by 1 year and *vice versa*. The result is presented in Table 32 which shows the average gain during 3 periods corresponding to the above mentioned age periods (1) the pre adolescent period during which the testes grow very slowly (2) the period *from 11–14 years during* which the greatest increment takes place, and (3) the period during which the growth rate decreases considerably

Conclusion

On the whole, it was not possible to *demonstrate* a significant difference in testes increment when the SA and CA respectively was increased, but in the intermediate age group, from 11–14 years of age, when the greatest increment occurs, there is a *significantly* greater increment when SA than when CA is increased by 1 year viz. 4 6 mm as compared with 2.2 mm (u = 2.1)

Chapter 12

Studies of Penis Development

Table 33 shows, for Quaade's (1955) and the present material the variation in penis length with age. The results of the two studies are very similar

Table 34 and Fig 42 give, for the present material, the *average length of the penis at the different chronological ages* Up to the age of 12 years the penis grows but slowly from 12–15 years rapidly and thereafter the growth rate gradually slows down.

Fig 43 illustrates the *relation between penis length and skeletal age* This curve is of approximately the same shape as that in Fig 42 but steeper during the period of maximum growth It is apparent, particularly from the velocity curves in Figs. 44 and 45 that the peak increment is greater when measured in SA than in CA. This might indicate a greater correlation between penile growth and SA than between penile growth and CA.

To assess more closely the relation between penile growth and CA as well as between penile growth and SA the author studied the average increment when SA was held constant and CA increased by 1 year and *vice versa*

The result is apparent from Table 35 Just as for the testes, the average increment during 3 periods was calculated (1) the pre-adolescent period during which the penis grows very slowly (2) the period from 12–15 years during which the greatest increment occurs, and (3) the period during which the growth rate decreases considerably

from [illegible] to 14 years	+2.6	+3.7 ± 1.6	+11.2	+7.5 ± 1.8
from 14 to 15 years	+0.6		+3.5	
from 15 to 16 years	+0.4		+0.2	
from 16 to 17 years	+2.8	2.3 ± 3.3	+5.6	1.7 ± 3.1
from 17 to 18 years	+[illegible].2		+5.5	
	Total	1.8 ± 0.8	Total	3.1 ± 0.9

Conclusion

On the whole, it was not possible to demonstrate any difference in penis growth when the SA and CA respectively was increased. Within the intermediate age period 12–15 years, when the maximum growth takes place there is a tendency to a greater increment when the SA than when the CA is increased by 1 year 7.5 and 3.7 mm respectively, but this difference is not significant (u = 1.6)

Chapter 13

Studies of the Age of Voice Change and Appearance of Moustache

Change of Voice

The relationship between the change of voice and CA on the one hand and SA on the other as found in the present material is shown in Table 36 and in Figs. 46 and 47. In 50 % of the boys the voice had broken at chronological age 15 1/2 and at skeletal age 15 years. This difference of 6 months is presumably due to the fact that skeletally the present children were retarded by 6 months in relation to the Brush Foundation material.

In Quaade's (1955) material the voice had broken at an average age of 15 years. According to Tanner the change of voice takes place at the time that the penis is about to complete its development. This occurred in the present material at 15–16 years of age.

The curve in Fig. 47 is steeper than that in Fig. 46 indicating perhaps a

Table 36

from [illegible] to 13 years	+8.4	from 12 to 13 years	+3.5
from 13 to 14 years	+17 4	from 13 to 14 years	+43 0
from 14 to 15 years	−3 9	from 14 to 15 years	+20.8
from 15 to 16 years	+5.6	from [illegible] to 16 years	−1 4
from 16 to 17 years	−27.2	from 16 to 17 years	+12.6
Total	+3.8 ± 6 5	Total	+20.7 ± 6 4

Table 38 and in Figs. 48 and 49 A moustache had appeared in 50 % at chronological age 14 /4 years and at skeletal age approx. 13³/ years.

The time of appearance of moustache in Quaade s (1955) material was about 15 years.

The curve illustrating the relationship between the appearance of a moustache and skeletal age is steeper than the curve plotting the appearance of moustache against chronological age. This indicates *a higher correlation between growth of beard and skeletal age than between growth of beard and chronological age*

The average increase in the percentage of boys who had acquired a moustache when the SA and CA respectively was increased by 1 year is shown in Table 39 There is a marked tendency to a higher correlation between SA and the appearance of a moustache than between CA and the appearance of a moustache, but the difference is not significant (u = 1 9)

Chapter 14

Skeletal Maturation and Social Conditions

It is generally assumed that the growth and development of children is determined by genetic as well as environmental factors.

The important role of *heredity* in growth and development has been demonstrated int al by Reynolds & Schoen in longitudinal studies of monozygotic triplets aged 8–18 years.

Their studies clearly showed the extremely uniform maturational patterns, there being no differences in height increment, skeletal maturation time of appearance of secondary sex characters, or time of eruption of teeth.

Hormonal production in the endocrine glands, governed by genetic as well as external factors, plays a decisive role in normal growth and development. This is known from endocrinology, in particular paediatric endocrinology as abnormalities in hormone production and in the mutual interaction of the hormones cause primarily disturbances of growth and development.

External factors which may affect growth are nutrition general hygiene including housing and diseases.

A comprehensive literature has accumulated on studies aiming at elucidating the influence of conditions of living upon height gain but only a few have been concerned with the influence of living conditions upon skeletal maturation The most important of these studies will be reviewed below

Todd found that the *social conditions* of children *influence their skeletal maturation* By selecting for the Brush Foundation study children from the best social circumstances who had always been in good health, he tried as far as possible to reduce the variations in skeletal maturation which is caused by differences in external factors.

Greulich (1951) studied the height weight and skeletal maturity of 1800 school children aged 6–17 years in the isle of Guam which was occupied by Japanese forces during World War II Conditions of living especially in respect to nutrition, were rather poor at that time. Skeletal age was assessed by the Greulich & Pyle atlas method Both boys and girls proved to be skeletally retarded as compared with the Brush Foundation children the boys by an average of 21 months and the girls by an average of 14 months They were retarded also in height and weight, the boys more so than the girls.

This phenomenon viz. that male *individuals are more susceptible than*

females to unfavourable external conditions, is known from the higher perinatal mortality among boys than among girls.

Stuart (cited by Greulich & Pyle 1959) studying the skeletal age of children in Boston, 50–60 from each group, found the boys to be retarded by an average of 2 months in relation to the Brush Foundation material. The mean standard deviation was 12.0 months. The girls were retarded by an average of 3 months. The mean SA was 11.3 months.

Sutow in 1952, set up standards of the skeletal maturation of the hand on the basis of 2370 healthy Japanese children aged 6–19 years. Assessing his standards by the Greulich & Pyle atlas method he found the Japanese girls to be retarded by an average of 17 months as compared with the American girls of the Brush Foundation study and the boys by an average of 14 months.

Greulich (1951) felt that this retardation was due rather to poor conditions of living than to racial differences.

This assumption is supported by a study performed by Greulich in 1956–1957 on 898 children born in America, but of Japanese parents. Their height, weight, and skeletal age were compared with the findings of Sutow in Japanese children in Japan 1952. The Japanese children born in U.S.A. were significantly taller heavier and skeletally more advanced than the Japanese children born in Japan. Comparison of the SA in the American-born Japanese children with the SA in the children of the Brush Foundation study showed the Japanese boys aged 5–7 years to be significantly retarded in skeletal age, average 7.0 months. At 13–17 years of age they were significantly advanced, average 8.5 months. At intermediate ages there was no significant difference. The Japanese girls born in U.S.A. were significantly advanced in relation to the American Brush Foundation children in the age range 10–17 years, average 10.0 months, but at other ages there was no significant difference.

These findings, in particular the similarity in skeletal maturity between American-born Japanese and the Brush Foundation children, should urge to caution in explaining a retarded growth in children from the less favoured parts of the world by racial differences.

Dreizen et al. (1957 b) studied the *importance of nutrition to the maturation of the hand skeleton* by investigating skeletal maturation in children exhibiting clinical signs of severe nutritional disturbances, such as pellagra dermatitis, beriberi neuritis, cheilosis, ocular signs in riboflavin deficiency and scurvy.

In 54 boys and 64 girls he found an average skeletal retardation of 13.5 and 12.0 months respectively while in a healthy control group of 53 boys and 80 girls he found a retardation of 0.5 and 0.6 months. This material was derived from the Nutrition Clinic, Hillmann Hospital, Birmingham, Alabama.

In 1954 Dreizen et al. had demonstrated the importance of nutrition to skeletal maturation in 160 children with clinical signs of nutritional dis-

Chapter 14

Skeletal Maturation and Social Conditions

It is generally assumed that the growth and development of children is determined by genetic as well as environmental factors.

The important role of *heredity* in growth and development has been demonstrated int. al. by Reynolds & Schoen in longitudinal studies of monozygotic triplets aged 8–18 years.

Their studies clearly showed the extremely uniform maturational patterns there being no differences in height increment, skeletal maturation time of appearance of secondary sex characters, or time of eruption of teeth

Hormonal production in the endocrine glands, governed by genetic as well as external factors, plays a decisive role in normal growth and development. This is known from endocrinology, in particular paediatric endocrinology as abnormalities in hormone production and in the mutual interaction of the hormones cause primarily disturbances of growth and development.

External factors which may affect growth are nutrition, general hygiene including housing and diseases.

A comprehensive literature has accumulated on studies aiming at elucidating the influence of conditions of living upon height gain but only a few have been concerned with the influence of living conditions upon skeletal maturation. The most important of these studies will be reviewed below

Todd found that the *social conditions* of children *influence their skeletal maturation* By selecting for the Brush Foundation study children from the best social circumstances who had always been in good health he tried as far as possible to reduce the variations in skeletal maturation which is caused by differences in external factors.

Greulich (1951) studied the height, weight and skeletal maturity of 1800 school children aged 6–17 years in the isle of Guam which was occupied by Japanese forces during World War II Conditions of living especially in respect to nutrition, were rather poor at that time. Skeletal age was assessed by the Greulich & Pyle atlas method Both boys and girls proved to be skeletally retarded as compared with the Brush Foundation children the boys by an average of 21 months and the girls by an average of 14 months. They were retarded also in height and weight, the boys more so than the girls.

This phenomenon, viz. that male individuals are more susceptible than

a significant positive correlation between the height of parents and children, independent of the income, and a significant—though smaller—positive correlation between children's height and their parents' income, when the parents' height was held constant.

In England Hammond's (1953) study on the height of 2925 children from private schools and council schools in slum districts showed that the children from private schools were 1–3 height years taller than the children from slums.

Berry & Cowin (1954) measuring the height of 14 year-old boys in private schools and in council schools found an average height of 166.5 ± 6.8 cm and 158.3 ± 8.9 cm respectively.

The increase in adult height which has taken place is due predominantly to improved social circumstances. This has been demonstrated by Acheson & Fowler (1964) in a study of the difference in height between two generations in a part of London where the standard of living had not changed appreciably as well as in a mining village in Wales where the standard of living had improved considerably in the course of the past 20 years. The difference between parents' height and the children's adult height (predicted on the basis of skeletal age assessment by Greulich & Pyle's atlas and Bayley Pinneau's height tables) was greater in Wales than in London.

The influence of social factors upon the time of the menarche has also been studied—in Norway by Schiøtz in 1928. He found the menarche in 2,008 girls from the higher social strata to have occurred an average of 3 months earlier than in 7 161 girls from socially lower classes in Oslo.

Bojlén et al. could just demonstrate a significant difference in the time of menarche, when grouping the girls by father's occupation the menarche occurring earlier in the socially better off groups.

Influence of Disease Upon Skeletal Maturation

From the papers of Dreizen et al. (1954) it is apparent that nutritional defects which are so severe as to cause clinical signs also cause retardation of skeletal maturation.

Meredith & Knott (1962) made semi-annual measurements of the height of 66 boys from the age of 5 to 10 years and of 73 girls from the age of 5 to 9 years. All these children were of higher social classes. The 20 % who had a history of least illness, mainly children's diseases, and colds and the 20 % who had a history of most illness, e. g. asthma, mild polio otitis, sinusitis, bronchitis, or acute nephritis in the course of the study period, were picked out and their height increment compared. The children of the group with most illness did not show a slower growth than the healthiest children.

In 87 children with congenital isolated ventricular septal defect Sandoe (1963) found no definite influence upon height.

Summing up, these investigations have shown a connection between less favourable social circumstances and retarded skeletal maturation—less fa-

turbances. All the children showed retarded skeletal maturity. All 28 ossification centres in the hand and wrist were retarded, but in different degrees. 82 of these children were given for 6 months 2 litres of milk in addition to their usual diet. Repeated determination of skeletal age showed that during these 6 months growth had been 1.7 times faster than normal. Those centres which according to the child's age were expected to grow fastest gave the best response to the treatment.

Prader, Tanner & van Harnack (1963) have called this phenomenon —viz. that after a period of retarded growth because of illness or starvation children show a tendency to make up for the loss and to follow their own previous growth curve—the catch up phenomenon.

Achesen & Hewitt (1954) in a longitudinal study of boys and girls aged 1 ¹/₂–5 years, made 2828 assessments of height and skeletal age and grouped the children into two social classes according to their father's occupation. They found the children of the socially higher class to be advanced in relation to children from the socially lower class, in respect to skeletal development as well as height. There was less difference between the girls than between the boys of the two classes. No attempt is made to explain this fact, but it is in keeping with Greulich's (1951) finding that boys are more vulnerable than girls to unfavourable external circumstances.

In Scandinavia the *influence of social factors upon height* has been investigated by Key in 1891. Measuring the height of 18 000 boys and girls in Stockholm from private as well as from council schools, he found the children from the council schools to be smaller than those from the private schools. The difference was less marked in the girls.

Measurements of the height of 20 000 conscripts (S. Hansen 1907–1911) showed that the average height varied according to occupation, the shortest being the tailors, average height 165 cm, and the tallest ones the students, average height 173 cm.

Broman, Dahlberg & Lichtenstein, comparing the height of children in private schools and in council schools, found the former children to be an average of about 3 cm taller than the latter.

Abrahamson (1950) in a study of the height of 871 boys in Stockholm related height to the father's income as well as to his occupation. No correlation was found between height and income, but a significant difference in height when related to occupational groups.

Dossing, whose material comprised 62,534 measurements of [illegible] 766 boys and 66 164 measurements of [illegible] 673 girls from 59 council schools and 3 grammar schools in Copenhagen, divided his material by income into well-to-do, poor and others. For boys as well as for girls, he found that the children from well-to-do families were an average of 1.5 cm taller than the children from the poor families, i.e. a difference so slight that income *per se* does not seem to influence height.

Quaade (1956) investigated the influence of income and of heredity upon the height of 3 771 children. He found

from the taxation authorities. For each family it was stated, in a code, whether for the year 1964–1965 the assessed taxable income had been between 0 and 5000 kroner between 5000 and 10,000 kr between 10 000 and 20 000 kr etc.

In the case of 3 boys and 16 girls it was not possible to procure data concerning social circumstances. Their families could not be found through the National Registry or else they were domiciled in municipalities that did not wish to supply the named information.

For comparison, Table 42 gives the distribution of assessed taxable income *for all 249 155* supporters in the municipality of Copenhagen for the year 1964–65 This table also includes supporters who have no children at school.

In order to ascertain whether differences in social circumstances influence skeletal maturation, the material was grouped by *skeletal maturation* and *occupation* in Tables 43 and 44 Skeletal maturation is given in 3 categories one group with average skeletal maturity one skeletally advanced, and one skeletally retarded. In practice, this grouping was done by picking out to represent average skeletal maturity children whose skeletal age corresponded to their chronological age in terms of whole completed years. Children whose chronological age was above their skeletal age were grouped as retarded and those who were younger than their skeletal age as advanced.

From Tables 43 and 44 it is apparent that in the higher social classes the number of children with retarded

vourable social circumstances and late menarche.

It is apparent also that the less favourable social circumstances relate *more to occupation than to income*, although it cannot be said which factors are decisive.

There is no doubt that nutrition influences weight and skeletal maturation.

Finally it may be pointed out, as done by several previous authors, that social circumstances need not consist *only of external factors*" but may well contain genetic factors.

Present Studies of the Influence of Social Factors Upon Skeletal Maturation

Table 40 gives the distribution of the present material by occupation. This grouping is in accordance with Svalastoga (1959)

Table 41 lists the distribution by income. Information concerning occupation as well as income was obtained

skeletal maturity decreases, while in the working classes it increases. Within the group of clerks and shop assistants the percentage of skeletally advanced retarded and average children is the same as in all occupational groups together

It was natural therefore, in the more detailed analysis to operate with only three social classes

(I) Professional, managerial teachers, artists, superior non-professionals, salaried employees, and small tradesmen

(II) *Clerks and shop assistants.*

(III) Skilled and unskilled labourers.

The groups of housewives and disablement pensioners were left out, as they are recruited from all social classes.

Tables 45 and 46 show for boys and girls respectively the distribution by skeletal maturity and these 3 occupational groups. With decreasing status there is an increased percentage of skeletally retarded children and a correspondingly decreasing percentage of advanced ones. This difference is significant for boys as well as girls.

When considering boys and girls in one group and this is permitted as *the distribution by parents occupation* is approximately the same for boys and

girls we find an even clearer significance beyond the 0 1 % limit (Table 47)

Also, it was investigated whether the *income* influenced skeletal maturation (Tables 48 and 49) In these tables all persons with assessed taxable incomes below 20 000 kroner (about £ 1 000) are assembled in one group and all with incomes above 20 000 in another This limit was not fixed at a lower level, as the group with an income below 10 000 kroner in the relevant occupational groups comprised only 38 families.

For boys as well as girls there is a tendency for the percentage with retarded skeletal maturity to rise with decreasing income, but this difference is not significant, also not when calculated for girls and boys together (Table 50) χ^2 is 4 9 and ought to be 6 0 to be significant. In other words, it was not possible to demonstrate that the income had a significant influence upon skeletal maturation.

Within the individual occupational groups there was also no significant dependence between skeletal maturity and income (Table 51)

Tables 52 53 and 54 show for boys, girls, and both sexes, the skeletal maturity according to whether or not their *mothers were employed* No significant dependence was found not either within the individual occupational groups (Table 55)

Lastly it was analysed whether a dependence could be found between skeletal maturity and *crowded flats* defined as flats or houses occupied by at least 2 persons per room Tables 56 57 and 58 show the distribution for boys, girls, and both sexes.

As far as the boys are concerned there is a significantly larger number of skeletally retarded among those from crowded flats. The girls show the same tendency but among them the findings are not significant. When boys and girls are considered together there is a significantly larger number of skeletally retarded children in crowded flats.

In an attempt to ascertain whether housing *per se is a factor of influence* and to investigate whether children with poor housing are socially worse off also in other respects—as this might increase the tendency to retardation

girls, we find an even clearer significance, beyond the 0.1 % limit (Table 47).

Also it was investigated whether the *income* influenced skeletal maturation (Tables 48 and 49). In these tables all persons with assessed taxable incomes below 20 000 kroner (about £ 1 000) are assembled in one group and all with incomes above 20 000 in another. This limit was not fixed at a lower level as the group with an income below 10 000 kroner in the relevant occupational groups comprised only 38 families.

For boys as well as girls there is a tendency for the percentage with retarded skeletal maturity to rise with decreasing income, but this difference is not significant, also not when calculated for girls and boys together (*Table 50*). χ^2 is 4.9 and ought to be 6.0 to be significant. In other words, it *was not possible to demonstrate that* the income had a significant influence upon skeletal maturation.

Within the individual occupational groups there was also no significant *dependence* between skeletal maturity and income (Table 51).

Tables 52, 53 and 54 show for boys, girls, and both sexes, the skeletal *maturity according to whether or not* their *mothers were employed*. No significant dependence was found, not either within the individual occupational groups (Table 55).

Lastly it was analysed whether a dependence could be found between skeletal maturity and *crowded flats* defined as flats or houses occupied by at least 2 persons per room. Tables 56, 57 and 58 show the distribution for boys, girls, and both sexes.

As far as the boys are concerned there is a significantly larger number of skeletally retarded among those from crowded flats. The girls show the same tendency, but among them the findings are not significant. When boys and girls are considered together there is a significantly larger number of skeletally retarded children in crowded flats.

In an attempt to ascertain whether housing *per se* is a factor of influence and to investigate whether children with poor housing are socially worse off also in other respects—as this might increase the tendency to retardation—

the material was further sub-divided by skeletal maturity housing, and occupation (Table 59).

This revealed that in the upper social classes crowding does not increase the tendency to retardation, while in the lower social classes crowding is of a distinct significance.

Conclusion

With falling social status the percentage of skeletally retarded children increases significantly.

In addition, there is a tendency for the percentage of retarded children to increase with decreasing income, but this difference is not significant.

The children's skeletal maturation is not demonstrably influenced by whether or not their mothers are employed.

Children living in crowded flats are skeletally more retarded than children living in non-crowded flats, but this applies only to the occupational group of skilled and unskilled labourers.

British material represents a wide section of all social classes.

Tanner & Whitehouse's system does not appear to afford a more accurate assessment than does Greulich & Pyle's atlas, even though each individual bone is rated according to its assessed maturity. The standard deviation of the skeletal age assessment is the same with Tanner & Whitehouse's method as with Greulich & Pyle's. The difference between skeletal age and chronological age also varies in the different age groups when the Tanner & Whitehouse system is used. The reason why Tanner & Whitehouse's system does not permit a more accurate determination of skeletal age is presumably that their rating system, in the form recommended so far, does not pay sufficient regard to differences in the growth rate of the individual bones at different times (cf. pp. 41–42).

Practical Application of Skeletal Age Assessment

In practice, the skeletal age may be assessed on a single X-ray film with an accuracy of about 6 months. Such a single assessment is required when a child's general maturity is to be evaluated, e.g. in certain endocrine disturbances, but also for cross-sectional studies of the development of children and adolescents in a population.

Reading of a series of X-ray films of the hand skeleton taken of the same child at intervals of e.g. 6 months allows a more accurate assessment of skeletal maturity than does a single reading, because in serial films it is possible to compare the sequence in a development. This procedure may be used when a given child's skeletal maturation is to be followed, for instance because a child is retarded, and treatment is being administered to accelerate the development. Frequently this is hormone therapy of children with endocrine disturbances.

Assessment of skeletal age is used also in trying to predict a child's adult height. By Bayley-Pinneau's height tables it is possible, at least for normal children, to predict with fair accuracy the adult height, if the child's height and skeletal age, according to Greulich & Pyle's atlas, are known. This method is too inaccurate for children under 6–7 years of age. The importance of being able to predict the adult height may be exemplified by the fact that Tanner has investigated children from the Royal Ballet School and can predict the adult height with an accuracy of a few cm. Therefore, children who are estimated to attain an adult height outside the permitted limits can stop attending the ballet school.

Factors Influencing Skeletal Maturation

Severe disease (Dreizen et al. 1954), heredity (Pryor 1907, Reynolds 1943, Reynolds & Schoen 1947), sex, hormone production, and social circumstances are assumed to influence skeletal maturation. Children with severe diseases were excluded from the present material. The influence of genetic factors upon skeletal maturation may perhaps be indirectly estimated by

Chapter 15

Discussion and Conclusions

Assessment of Skeletal Age

The present study has shown that Greulich & Pyle's atlas is applicable for the assessment of skeletal age in Danish children. However, the skeletal maturity in the present material of school children, close to the socio-economic average in Copenhagen, was retarded by an average of about 6 months in relation to the American children who formed the basis of Greulich & Pyle's atlas.

In using the Greulich & Pyle atlas on Danish children, therefore, it must be borne in mind that a child of average maturity has a skeletal age which is about 6 months below its chronological age.

The reason why the children in Copenhagen are skeletally retarded as compared with the American children is presumably that the children of the American material were recruited from homes that were in all respects above average. The maturation of these children, examined a generation ago, took place even earlier than the present average maturation of American children.

The average skeletal retardation in the present material was 5.9 months for boys and 5.2 months for girls, in some age groups somewhat lesser, in others greater. This variation in the difference between skeletal and chronological age, also apparent in other studies (Greulich 1951, 1957), may be due to some heterogeneity in the assessment, since skeletal age is easier to assess in some age groups than in others. This means that where certain skeletal ages are concerned a systematic error may have been introduced, an error which changes only the mean value without influencing the standard deviation.

However, the variation in the difference between skeletal and chronological age may also be due to some heterogeneity of the materials. All the standards in Greulich & Pyle's atlas are perhaps not equally representative of the age group which they are supposed to represent, and the skeletal maturity in a single age group of the present material might happen to be more—or less—retarded than the average for the entire material.

The use of Tanner & Whitehouse's system for assessing skeletal development showed the skeletal maturity in the present material to be advanced by an average of 2.3 months in relation to the children on whom Tanner & Whitehouse based their method. The

voice are concerned, the difference is significant, and for the beard the tendency to a higher correlation to skeletal age than to chronological age is very distinct. Such a correlation was indeed to be expected, as both skeletal maturation and the appearance of the various puberal signs in boys are due to the androgen production in the testes and adrenals. The fact that for the *beard* there was only a tendency to a higher correlation to skeletal than to chronological age, and not a significant difference, may be due to inaccuracy in the measurement and to individual factors of genetic nature.

For *breast* development no significantly higher correlation to skeletal than to chronological age was found. The explanation may be difficulty in assessing the degree of breast development. The size and shape of the breasts are also influenced by inherited factors. Lastly the maturation of the breast is influenced not only by oestrogenic hormone, but also by prolactin, progesterone, and growth hormone which exert very little or no effect upon skeletal maturation.

That a dependence exists at all between the various maturational criteria and chronological age, when skeletal age is held constant, may be explained largely by the error of measurement in assessing skeletal age (cf pp. 62–63)

Thus, skeletal age is a better measure than chronological age of the stage of biological maturation. Skeletal age is also a better measure than height. The explanation is that a given skeletal age indicates how far a child has reached in the process of maturation, which terminates in closure of all epiphyses. On the other hand a given height does not indicate how great a percentage of its final height the child has attained, as its adult height is not known until the growth in length is completed. The various signs of puberty separately and together give a certain impression of the stage of development, but it is rather difficult to grade these criteria of maturity Therefore, determination of skeletal age is definitely justified in assessing biological maturity

Skeletal Maturation in Relation to Social Conditions

In the present study skeletal maturity was related to the supporter's occupation, to his assessed taxable income, to housing, and to the mother's employment, if any

With decreasing occupational status a significantly increasing percentage of children showed retarded skeletal maturity There was also a tendency for the percentage of children of retarded skeletal maturity to increase with decreasing income, but no significance was demonstrated. Furthermore, skeletal maturation in children living in crowded flats proved to be more retarded than in children from non-crowded flats. However this applies only to children whose fathers were of occupational group III skilled and unskilled labourers. Analysis of skeletal maturity according to whether or not the mothers were employed showed no significant difference.

These findings indicate that skeletal maturation, and thus also biological maturation in children of an average

comparing the pattern of growth and development of children with that of their parents, but the parents data carry considerable inaccuracy

Relation of Skeletal Maturation to Height and Sexual Development

As hormone production influences growth in height, sexual development, as well as skeletal maturation it seemed natural to study the relationship of various developmental criteria to skeletal maturation

Thyroid hormone is necessary for normal skeletal development. Primarily it appears to act upon the maturation of the bones and thus their shape, but—together with the growth hormone—it also causes longitudinal growth of the bones. The growth hormone is not believed to accelerate skeletal maturation.

The role of the sex hormones in skeletal maturation is presumably that androgens, from the adrenals as well as from the testes, accelerate growth in length in the epiphyses, but to an even greater extent skeletal maturation, including epiphyseal closure. Oestrogenic hormone accelerates epiphyseal closure (Wilkins 1965 Talbot, Sobel McArthur & Crawford 1952)

In the present study it was found that the various maturational criteria such as height menarche, breast development, pubic hair etc. occur at a skeletal age which according to the atlas of Greulich & Pyle, is about 6 months below the chronological age. This is in keeping with the fact that the present children were skeletally retarded by about 6 months as compared with the American material.

Moreover it was confirmed that a higher correlation exists between height and skeletal age than between height and chronological age and a higher correlation between sexual development and skeletal age than between sexual development and chronological age

The finding of a significantly higher correlation between *height increment and skeletal maturation than between* height gain and chronological age is explicable by the decisive influence of the thyroid hormone, growth hormone, and sex hormones upon body height as well as skeletal maturation.

A significantly higher correlation was found between the onset of *menarche* and skeletal age than between menarche and chronological age. This accords with the fact that the menarche is governed by the production of oestrogen which is also of importance to epiphyseal closure.

Furthermore, there was a significantly higher correlation between appearance of *pubic hair* and skeletal age than between pubic hair and chronological age—in boys as well as in girls. The explanation is presumably that androgens from the adrenal cortex in girls and androgens from the adrenal cortex and testes in boys influence the development of pubic hair as well as skeletal maturation.

In respect to the development of the *testes* the *change of voice* and *growth of beard* there was also a higher correlation to skeletal age than to chronological age. As far as the testes and the

voice are concerned, the difference is significant, and for the beard the tendency to a higher correlation to skeletal age than to chronological age is very distinct. Such a correlation was indeed to be expected, as both skeletal maturation and the appearance of the various puberal signs in boys are due to the androgen production in the testes and adrenals. The fact that for the *pubic hair* there was only a tendency to a higher correlation to skeletal than to *chronological age, and not a significant* difference, may be due to inaccuracy in the measurement and to individual factors of genetic nature.

For *breast* development no significantly higher correlation to skeletal than to chronological age was found. The explanation may be difficulty in assessing the degree of breast development. The size and shape of the breasts are also influenced by inherited factors. Lastly the maturation of the breast is influenced not only by oestrogenic hormone, but also by prolactin, progesterone, and growth hormone which exert very little or no effect upon skeletal maturation.

That a dependence exists at all between the various maturational criteria and chronological age, when skeletal age is held constant, may be explained largely by the error of measurement in assessing skeletal age (*cf. pp.* 62–65)

Thus, skeletal age is a better measure than chronological age of the stage of biological maturation. Skeletal age is also a better measure than height. The explanation is that a given skeletal age indicates how far a child has reached in the process of maturation, which terminates in closure of all epiphyses. On the other hand, a given height does not indicate how great a percentage of its *final height the child* has attained, as its adult height is not known until the growth in length is completed. The *various signs of* puberty separately and together give a certain impression of the stage of development, but it is *rather difficult* to grade these criteria of maturity. Therefore, determination of skeletal age is definitely justified in assessing biological maturity

Skeletal Maturation in Relation to Social Conditions

In the present study skeletal maturity was related to the supporter's occupation, to his assessed taxable income, to housing, and to the mother's employment, if any

With decreasing occupational status a significantly increasing percentage of children showed retarded skeletal maturity. There was also a tendency for the percentage of children of retarded skeletal maturity to increase with decreasing income, but no significance was demonstrated. Furthermore, skeletal maturation in children living in crowded flats proved to be more retarded than in children from non-crowded flats. However this applies *only to children whose fathers* were of occupational group III skilled and unskilled labourers. Analysis of skeletal maturity *according to* whether or not the mothers were employed showed no significant difference.

These findings *indicate that* skeletal maturation, and thus also biological maturation in children of an average

socio-economic level in Copenhagen depends but slightly upon the supporter's income, but to a far greater extent upon his occupation

A difference in the incidence of illness in the various occupational groups might explain this difference in skeletal maturation However this is unlikely as it has been demonstrated that only severe diseases influence skeletal maturation—and children with severe diseases were excluded from the present study

This dependence of skeletal maturation upon occupation is more likely to be due to the fact that different occupational groups have different ways of living Very probably there is a question of a difference in nutrition (cf p 103), but this can only be proved by long lasting well-controlled dietary analyses.

Summary

In the *introduction* the extent and aim of the study are described. The investigations consisted of a cross-sectional study of skeletal maturation of the hand and wrist in a series of Danish school children aged 7–18 years. An attempt was made to correlate skeletal maturity to chronological age, height, stage of sexual development, and the environment in which the children were raised. The results were compared with those of corresponding studies from other countries.

The object of the study was to investigate whether various foreign systems for skeletal age assessment are applicable to Danish children. The value of skeletal maturity as a measure of biological maturity was studied, and lastly it was evaluated whether the differences in social circumstances found in this material influenced the skeletal maturation.

Chapter 1 gives a review of previous studies on the skeletal maturation of the hand and wrist, in particular the onset and sequence of ossification centres and of epiphyseal fusion with the shafts. Various systems for assessing skeletal age are based upon the skeletal maturation in the hand, foot, knee, or hip or in the six areas hip, knee foot, shoulder elbow and hand Particular attention is given to Greulich & Pyle's atlas and Tanner & Whitehouse's system for estimating the maturity of the hand skeleton—the two methods applied to the present material The reasons for studying skeletal maturation in the hand and wrist are advanced

Chapter 2 deals with the methods for assessing the development of various sex characters in boys and girls.

Chapter 3 presents the material which comprises 477 boys and 532 girls in the age range 7–18 years.

Chapter 4 describes the method, i.e. examination by X-ray of the right hand, measurement of standing height and for the boys measurement of the length of the testes and penis and assessment of the stage of pubic hair development, moustache and voice—for the girls history-taking of the time of menarche and assessment of the stage of breast and pubic hair development.

In *chapter* 5 the procedure of assessing skeletal age by the atlas of Greulich & Pyle and by the method of Tanner & Whitehouse are described. Certain difficulties in assessing the carpal bones by the latter method are demonstrated.

Chapter 6 submits the results of

socio-economic level in Copenhagen depends but slightly upon the supporter's income, but to a far greater extent upon his occupation.

A difference in the incidence of illness in the various occupational groups might explain this difference in skeletal maturation However this is unlikely as it has been demonstrated that only severe diseases influence skeletal maturation—and children with severe diseases were excluded from the present study

This dependence of skeletal maturation upon occupation is more likely to be due to the fact that different occupational groups have different ways of living Very probably there is a question of a difference in nutrition (cf p 103) but this can only be proved by long-lasting well-controlled dietary analyses.

Summary

In the *introduction* the extent and aim of the study are described. The investigations consisted of a cross-sectional study of skeletal maturation of the hand and wrist in a series of Danish school children aged 7–18 years. An attempt was made to correlate skeletal maturity to chronological age, height, stage of sexual development, and the environment in which the children were raised. The results were compared with those of corresponding studies from other countries.

The object of the study was to investigate whether various foreign systems for skeletal age assessment are applicable to Danish children. The value of skeletal maturity as a measure of biological maturity was studied, and lastly it was evaluated whether the differences in social circumstances found in this material influenced the skeletal maturation.

Chapter 1 gives a review of previous studies on the skeletal maturation of the hand and wrist, in particular the onset and sequence of ossification centres and of epiphyseal fusion with the shafts. Various systems for assessing skeletal age are based upon the skeletal maturation in the hand, foot, knee, or hip or in the six areas hip, knee, foot shoulder elbow and hand. Particular attention is given to Greulich & Pyle's atlas and Tanner & Whitehouse's system for estimating the maturity of the hand skeleton—the two methods applied to the present material. The reasons for studying skeletal maturation in the hand and wrist are advanced.

Chapter 2 deals with the methods for assessing the development of various sex characters in boys and girls.

Chapter 3 presents the material which comprises 477 boys and 532 girls in the age range 7–18 years.

Chapter 4 describes the method, i.e. examination by X-ray of the right hand, measurement of standing height, and for the boys measurement of the length of the testes and penis and assessment of the stage of pubic hair development, moustache and voice—for the girls history-taking of the time of menarche and assessment of the stage of breast and pubic hair development.

In *chapter 5* the procedure of assessing skeletal age by the atlas of Greulich & Pyle and by the method of Tanner & Whitehouse are described. Certain difficulties in assessing the carpal bones by the latter method are demonstrated.

Chapter 6 submits the results of

socio-economic level in Copenhagen depends but slightly upon the supporter's income, but to a far greater extent upon his occupation

A difference in the incidence of illness in the various occupational groups might explain this difference in skeletal maturation However this is unlikely as it has been demonstrated that only severe diseases influence skeletal maturation—and children with severe diseases were excluded from the present study

This dependence of skeletal maturation upon occupation is more likely to be due to the fact that different occupational groups have different ways of living Very probably there is a question of a difference in nutrition (cf p 103), but this can only be proved by long lasting well-controlled dietary analyses.

on the age at menarche. It is clearly apparent that the menarche is occurring ever earlier The age at menarche for the girls of the present series averaged 13 /4 years in terms of chronological age and $12^{3}/_{4}$ *in terms of skeletal age*. This difference of [illegible] months is due to the fact that skeletally the Danish material was retarded by about 6 months in relation to the Brush Foundation material.

There is a significantly higher correlation between skeletal age and age at menarche than between chronological age and age at menarche.

Chapter 9 deals with the development of the breasts. In the girls of the present material this development started, on the average, at a chronological age of 10.8 years and a skeletal age of 10.2 years. As far as breast maturation is concerned too there was a tendency to a greater dependence upon skeletal than upon chronological age, but this difference is not significant.

Chapter 10 deals with the development of pubic hair In the girls it appears on the average at a chronological age of 11.6 years and a skeletal age of 11.0 years. In the boys of the present series pubic hair started appearing at an average chronological age of 12.8 years and skeletal age 12.4 years. For girls as well as boys there was a significantly higher correlation between pubic hair and chronological age.

Chapter 11 submits the results of measurements of the testes. The peak increment took place in the age 11–14 years. It applies to this age group that the correlation between testicular growth and skeletal age was significantly higher than between testicular growth and chronological age.

From *chapter 12* it is apparent that the growth of the penis takes place mainly at the age 12–15 years. There is a tendency to a higher correlation between increase in penis size and skeletal age than between increase in penis size and chronological age, but the difference is not significant.

In *chapter 13* it is reported that the voice change occurred in the boys of the present series at an average chronological age of $15^{1}/_{4}$ years, skeletal age 15 years. A moustache appears on the average at chronological age $14^{1}/_{4}$ years and skeletal age $13^{3}/_{4}$ years. There is a significantly higher correlation between voice change and skeletal age than between voice change and chronological age. There is a marked tendency for the appearance of a moustache to be more closely correlated to skeletal than to chronological age, but a significant difference could not be demonstrated.

Chapter 14 first gives an account of various factors, such as heredity nutrition, disease, and hormone production, which may influence maturation, including skeletal maturation. In the present study skeletal maturation was considered in relation to supporter's occupation, assessed taxable income, housing and to mother's employment, if any With decreasing occupational status there was a significantly increasing percentage of children of retarded skeletal maturity There was also a tendency for the percentage of retarded children to increase with decreasing income, but no significance was demonstrated.

skeletal age assessment according to the Greulich & Pyle atlas and the Tanner & Whitehouse method. Two series of skeletal ages assessed by the Tanner & Whitehouse method are given. These series are identical for the younger ages, but from the 13th birthday of the boys and the 11th birthday of the girls a new assessment was made because of the difficulties in evaluating the carpal bones.

According to Greulich & Pyle's atlas the boys of the present series are retarded by an average of 5.9 months in relation to the material upon which the atlas was based and the girls by an average of 5.2 months.

Assessed by the method of Tanner & Whitehouse the present material is advanced by an average of 2.3 months in relation to the children examined by Tanner & Whitehouse. This applies to boys as well as to girls. The standard deviation of the skeletal age determination by the atlas of Greulich & Pyle is 12.4 months for boys and 11.5 months for girls and by the method of Tanner & Whitehouse 13.0 months for boys and 10.8 months for girls. These values represent the average for all the studied age groups. The standard deviation comprises biological variation and error of measurement. The observed standard deviation is in the same range as reported by previous authors.

The variable error of the skeletal age assessment by the Greulich & Pyle atlas in the present material was 3–4 months, i.e. in the same range as found by others.

In the further investigations it was preferred to use the results of skeletal age assessment by the atlas of Greulich & Pyle, partly because this method is simple and quick to learn and use and partly because in the present study it proved just as accurate as the system of Tanner & Whitehouse.

In *chapters 7–13* an attempt is made to evaluate to what extent skeletal age is applicable as a measure of biological maturity by comparing it with other maturational criteria such as height, menarche, development of breasts and pubic hair etc..

The assessment of skeletal age as a measure of biological maturity was done by comparing the relation of the various maturational criteria to skeletal age with the relation of the same criteria to chronological age.

The curves illustrating the relation of the various maturational criteria to chronological age may be taken to represent normal development, in so far as it may be assumed that the present material is a representative section of children in the Danish population. The curves represent a snapshot of the development, as the study was cross-sectional.

In *chapter 7* various Norwegian, Swedish and American height tables are compared with the result of the present height measurements. The children of the present material were, measured in height years, about 6 months retarded in relation to the children of the Brush Foundation material which formed the basis of Greulich & Pyle's atlas. A significantly higher correlation was found between height and skeletal age than between height and chronological age

Chapter 8 reports previous studies

on the age at menarche. It is clearly apparent that the menarche is occurring ever earlier. The age at menarche for the girls of the present series averaged $13^1/_4$ years in terms of chronological age and $12^3/_4$ in terms of skeletal age. This difference of 6 months is due to the fact that skeletally the Danish material was retarded by about 6 months in relation to the Brush Foundation material.

There is a significantly higher correlation between skeletal age and age at menarche than between chronological age and age at menarche.

Chapter 9 deals with the development of the breasts. In the girls of the present material this development started, on the average, at a chronological age of 10.8 years and a skeletal age of 10.2 years. As far as breast maturation is concerned too, there was a tendency to a greater dependence upon skeletal than upon chronological age, but this difference is not significant.

Chapter 10 deals with the development of pubic hair. In the girls it appears on the average at a chronological age of 11.6 years and a skeletal age of 11.0 years. In the boys of the present series pubic hair started appearing at an average chronological age of 12.8 years and skeletal age 12.4 years. For girls as well as boys there was a significantly higher correlation between pubic hair and chronological age.

Chapter 11 submits the results of measurements of the testes. The peak increment took place in the age 11–14 years. It applies to this age group that the correlation between testicular growth and skeletal age was significantly higher than between testicular growth and chronological age.

From *chapter 12* it is apparent that the growth of the penis takes place mainly at the age 12–15 years. There is a tendency to a higher correlation between increase in penis size and skeletal age than between increase in penis size and chronological age, but the difference is not significant.

In *chapter 13* it is reported that the voice change occurred in the boys of the present series at an average chronological age of $15^1/_4$ years, skeletal age 15 years. A moustache appears on the average at chronological age $14^1/_4$ years and skeletal age $13^3/_4$ years. There is a significantly higher correlation between voice change and skeletal age than between voice change and chronological age. There is a marked tendency for the appearance of a moustache to be more closely correlated to skeletal than to chronological age, but a significant difference could not be demonstrated.

Chapter 14 first gives an account of various factors, such as heredity, nutrition, disease, and hormone production, which may influence maturation, including skeletal maturation. In the present study skeletal maturation was considered in relation to supporter's occupation, assessed taxable income, housing, and to mother's employment, if any. With decreasing occupational status there was a significantly increasing percentage of children of retarded skeletal maturity. There was also a tendency for the percentage of retarded children to increase with decreasing income, but no significance was demonstrated.

skeletal age assessment according to the Greulich & Pyle atlas and the Tanner & Whitehouse method. Two series of skeletal ages assessed by the Tanner & Whitehouse method are given These series are identical for the younger ages, but from the 13th birthday of the boys and the 11th birthday of the girls a new assessment was made because of the difficulties in evaluating the carpal bones.

According to Greulich & Pyle s atlas the boys of the present series are re tarded by an average of 5 9 months in relation to the material upon which the atlas was based and the girls by an average of 5 2 months.

Assessed by the method of Tanner & Whitehouse the present material is ad vanced by an average of 2.3 months in relation to the children examined by Tanner & Whitehouse. This applies to boys as well as to girls. The standard deviation of the skeletal age determi nation by the atlas of Greulich & Pyle is 12 4 months for boys and 11 5 months for girls and by the method of Tanner & Whitehouse 13 0 months for boys and 10 8 months for girls. These values represent the average for all the studied age groups. The stand ard deviation comprises biological va riation and error of measurement. The observed standard deviation is in the same range as reported by previous authors.

The variable error of the skeletal age assessment by the Greulich & Pyle atlas in the present material was 3–4 months, i.e. in the same range as found by others.

In the further investigations it was preferred to use the results of skeletal age assessment by the atlas of Greulich & Pyle, partly because this method is simple and quick to learn and use and partly because in the present study it proved just as accurate as the system of Tanner & Whitehouse.

In *chapters 7–13* an attempt is made to evaluate to what extent skele tal age is applicable as a measure of biological maturity by comparing it with other maturational criteria, such as height, menarche, development of breasts and pubic hair etc.

The assessment of skeletal age as a measure of biological maturity was done by comparing the relation of the various maturational criteria to skeletal age with the relation of the same cri teria to chronological age.

The curves illustrating the relation of the various maturational criteria to chronological age may be taken to re present normal development, in so far as it may be assumed that the present material is a representative section of children in the Danish population The curves represent a snapshot of the de velopment as the study was cross-sectional.

In *chapter 7* various Norwegian, Swedish and American height tables are compared with the result of the present height measurements. The chil dren of the present material were, measured in height years, about 6 months retarded in relation to the chil dren of the Brush Foundation material which formed the basis of Greulich & Pyle s atlas. A significantly higher cor relation was found between height and skeletal age than between height and chronological age.

Resumé

I *indledningen* gøres rede for arbejdets omfang og formål. Arbejdet omfatter en tværsnitsundersøgelse af skeletmodningen i hånd og håndled hos en række danske skolebørn i alderen 7 til 18 år. Knogleudviklingen er søgt korreleret til børnenes kronologiske alder, pubertetsudvikling og det miljø, hvori de er vokset op. De fundne resultater er sammenlignet med tilsvarende udenlandske.

Hensigten med arbejdet har været at undersøge, om forskellige udenlandske systemer til skeletalderbestemmelse kan anvendes på danske børn. Knogleudviklingens værdi som mål for børnenes biologiske udvikling undersøges, og endelig vurderes, om de i materialet fundne forskelle i sociale forhold har indflydelse på skeletudviklingen.

I *kapitel I* refereres tidligere undersøgelser over skeletudviklingen i hånd og håndled, specielt tidspunkterne og rækkefølgen for knoglekernernes optræden og for epifysernes sammenvoksning med diafyserne. Derefter omtales forskellige systemer til skeletalderbestemmelse, der bygger på knogleudviklingen i hånd, fod, knæ, hofte eller de seks områder hofte, knæ, fod, skulder albue og hånd. Greulich & Pyle s atlas og Tanner & Whitehouse s system til bestemmelse af håndskelet udviklingen gennemgås specielt, da det er disse to metoder der er anvendt på nærværende materiale. Det begrundes, at man specielt har valgt at undersøge skeletudviklingen i hånd- og håndled.

I *kapitel II* gennemgås metoder til vurdering af forskellige kønskarakterers udvikling hos drenge og piger

I *kapitel III* beskrives materialet, som består af 477 drenge og 532 piger i alderen 7 til 18 år

Kapitel IV indeholder beskrivelse af undersøgelsen, som omfattede røntgenfotografering af højre hånd, måling af stående højde, endvidere for drengenes vedkommende måling af testes' og penis længde samt vurdering af pubesbehåring, moustache og stemme, og for pigernes vedkommende anamnese vedrørende menarchens indtræden samt vurdering af mammaudvikling og pubesbehåring

I *kapitel V* redegøres for fremgangsmåden ved skeletalderbestemmelsen efter Greulich & Pyle s atlas og Tanner & Whitehouse s metode. Der påvises visse vanskeligheder ved vurdering af håndrodsknoglerne efter sidstnævnte metode.

I *kapitel VI* fremlægges resultaterne af skeletalderbestemmelsen efter Greulich & Pyle s atlas og Tanner & Whitehouse s metode. Der er angivet [illegible] serier

The skeletal maturation of children living in crowded flats was found to be more retarded than in children from non-crowded flats, but this applies only to children whose fathers belonged to occupational group III skilled and unskilled labourers

Analysis of skeletal maturation according to whether or not the mothers were employed showed no significant difference.

Chapter 15 comprises discussion and conclusions.

Resumé

I *indledningen* gøres rede for arbejdets omfang og formål. Arbejdet omfatter en tværsnitsundersøgelse af skeletmodningen i hånd og håndled hos en række danske skolebørn i alderen 7 til 18 år. Knogleudviklingen er søgt korreleret til børnenes kronologiske alder, pubertetsudvikling og det miljø, hvori de er vokset op. De fundne resultater er sammenlignet med tilsvarende udenlandske.

Hensigten med arbejdet har været at undersøge, om forskellige udenlandske systemer til skeletalderbestemmelse kan anvendes på danske børn. Knogleudviklingens værdi som mål for børnenes biologiske udvikling undersøges, og endelig vurderes, om de i materialet fundne forskelle i sociale forhold har indflydelse på skeletudviklingen.

I *kapitel I* refereres tidligere undersøgelser over skeletudviklingen i hånd og håndled, specielt tidspunkterne og rækkefølgen for knoglekernernes optræden og for epifysernes sammenvoksning med diafyserne. Derefter omtales forskellige systemer til skeletalderbestemmelse, der bygger på knogleudviklingen i hånd, fod, knæ, hofte eller i de seks områder: hofte, knæ, fod, skulder, albue og hånd. Greulich & Pyle's atlas og Tanner & Whitehouse's system til bestemmelse af håndskeletudviklingen gennemgås specielt, da det er disse to metoder, der er anvendt på nærværende materiale. Det begrundes, at man specielt har valgt at undersøge skeletudviklingen i hånd- og håndled.

I *kapitel II* gennemgås metoder til vurdering af forskellige kønskarakterers udvikling hos drenge og piger.

I *kapitel III* beskrives materialet, som består af 477 drenge og 532 piger i alderen 7 til 18 år.

Kapitel IV indeholder beskrivelse af undersøgelsen, som omfattede røntgenfotografering af højre hånd, måling af stående højde, endvidere for drengenes vedkommende måling af testes og penis længde samt vurdering af pubesbehåring, moustache og stemme, og for pigernes vedkommende anamnese vedrørende menarchens indtræden samt vurdering af mammaudvikling og pubesbehåring.

I *kapitel V* redegøres for fremgangsmåden ved skeletalderbestemmelsen efter Greulich & Pyle's atlas og Tanner & Whitehouse's metode. Der påvises visse vanskeligheder ved vurdering af håndrodsknoglerne efter sidstnævnte metode.

The skeletal maturation of children living in crowded flats was found to be more retarded than in children from non-crowded flats, but this applies only to children whose fathers belonged to occupational group III skilled and unskilled labourers.

Analysis of skeletal maturation according to whether or not the mothers were employed showed no significant difference.

Chapter 15 comprises discussion and conclusions.

træder tidligere og tidligere. Menarchealderen for pigerne i nærværende materiale er gennemsnitligt 13¹/₄ år målt i kronologisk alder og 12/₄ år målt i skeletalder. Forskellen på ¹/₂ år skyldes det forhold, at det danske materiale skeletmæssigt er retarderet med ca. ¹/₂ år i forhold til Brush Foundation materialet.

Der er signifikant større korrelation mellem skeletalder og menarchealder end mellem kronologisk alder og menarchealder.

Kapitel IX omhandler mammaudviklingen. Den begynder for nærværende materiales piger gennemsnitligt ved en kronologisk alder på 10,6 år og ved en skeletalder på 10,2 år. Man finder også for mammaudviklingens vedkommende en tendens til større afhængighed af skeletalder end af kronologisk alder, men forskellen er ikke signifikant.

Kapitel X omhandler pubesudviklingen. For pigernes vedkommende begynder den gennemsnitligt ved en kronologisk alder på 11,6 år og ved en skeletalder på 11,0 år. For drengenes vedkommende finder man for nærværende materiale, at pubesudviklingen gennemsnitligt begynder ved en kronologisk alder på 12,8 år og ved en skeletalder på 12,4 år. For såvel piger som drenge finder man en signifikant større korrelation mellem pubesudvikling og skeletalder end mellem pubesudvikling og kronologisk alder.

I *kapitel XI* fremlægges resultaterne af målinger af testes. Tilvæksten er størst i 11–14 års alderen. For denne aldersgruppes vedkommende gælder det, at der er signifikant større korrelation mellem testes vækst og skeletalder end mellem testes vækst og kronologisk alder.

Af *kapitel XII* fremgår, at væksten af penis især foregår i 12–15 års alderen. Der ses tendens til større korrelation mellem vækst af penis og skeletalder end mellem vækst af penis og kronologisk alder, men forskellen er ikke signifikant.

Af *kapitel XIII* fremgår, at stemmen hos drengene i nærværende materiale går i overgang ved en gennemsnitlig kronologisk alder på 15 ¹/₂ år og ved skeletalderen 15 år. Moustache fremkommer gennemsnitligt ved den kronologiske alder 14³/₄ år og ved skeletalderen 13³/₄ år. Der er signifikant større korrelation mellem stemmens overgang og skeletalder end mellem stemmens overgang og kronologisk alder. Der er en stærk tendens til, at fremkomsten af moustache er nærmere korreleret til skeletalder end til kronologisk alder, men der påvises ingen signifikans.

I *kapitel XIV* gøres først rede for forskellige faktorer som arv, ernæring, sygdom og hormonproduktion, der kan påvirke udviklingen, derunder skeletudviklingen. I nærværende undersøgelse har man sat skeletudviklingen i relation til forsørgerens erhverv, hans ansatte skattepligtige indkomst, til boligens størrelse samt til, hvorvidt moderen havde udeerhverv eller ej. Med faldende erhvervsmæssig status påviser man en signifikant større procentdel børn med retarderet knogleudvikling. Der findes også en tendens til, at procenten af retarderede stiger med faldende indkomst, men der påvises ingen signifikans.

Man finder videre, at knogleudviklin-

for skeletaldre, bedømt efter Tanner & Whitehouse s system. De er identiske for de lave aldre, men fra det fyldte 13 år for drengenes vedkommende og det fyldte 11 år for pigernes vedkommende er der foretaget en ny vurdering fordi vurderingen af håndrodsknoglerne var behæftet med visse vanskeligheder

Efter Greulich & Pyle s atlas er drengene i nærværende materiale retarderet med gennemsnitligt 5 9 måneder i forhold til materialet der ligger til grund for atlas, og pigerne med gennemsnitligt 5,2 måneder

Bedømt efter Tanner & Whitehouse s metode er nærværende materiale avanceret med gennemsnitligt 2,3 måneder i forhold til de af Tanner & Whitehouse undersøgte børn. Det gælder for både drenge og piger

Spredningen på skeletalderbestemmelsen, foretaget efter Greulich & Pyle s atlas, er 12 4 måneder for drenge og 11,5 måneder for piger og efter Tanner & Whitehouse s metode 13 0 måneder for drenge og 10 8 måneder for piger Tallene angiver gennemsnit for alle de undersøgte aldersgrupper Spredningen omfatter biologisk variation og målefejl. Den fundne spredning er af samme størrelsesorden som i tidligere arbejder

Den variable fejl på skeletalderbestemmelsen efter Greulich & Pyle s atlas i nærværende undersøgelse er 3–4 måneder og af samme størrelsesorden som hos andre undersøgere.

I det videre arbejde har man foretrukket at anvende resultaterne af skeletalderbestemmelsen foretaget efter Greulich & Pyle s atlas, dels fordi det er en simpel og hurtig metode at indøve og anvende, dels fordi den i nærværende undersøgelse har vist sig at være lige så nøjagtig som Tanner & Whitehouse s system

I *kapitlerne VII–XIII* har man søgt at vurdere i hvor høj grad skeletalderen kan anvendes som mål for den biologiske udvikling idet man har sammenholdt den med andre udviklingskriterier som højde, indtræden af menarche mamma og pubesudvikling m. m..

Vurderingen af skeletalder som mål for den biologiske udvikling foregår ved at sammenligne de forskellige udviklingskriteriers relation til skeletalderen med de samme kriteriers relation til den kronologiske alder

Kurverne over de forskellige udviklingskriteriers relation til den kronologiske alder kan tages som udtryk for den normale udvikling for så vidt som man kan antage, at nærværende materiale er et repræsentativt udsnit af børnene i den danske befolkning Kurverne viser et øjebliksbillede af udviklingen, idet undersøgelsen er udført som en tværsnitsundersøgelse.

I *kapitel VII* sammenlignes forskellige norske, svenske og amerikanske højdetabeller med resultatet af nærværende undersøgelses højdemålinger Børnene i nærværende undersøgelse er målt i højdeår ca. et halvt år retarderet i forhold til børnene i Brush Foundation materialet, som ligger til grund for Greulich & Pyle s atlas. Der er på vist signifikant større korrelation mellem højde og skeletalder end mellem højde og kronolgisk alder

I *kapitel VIII* refereres tidligere undersøgelser over menarchealderen. Det fremgår tydeligt at menarchen ind

træder tidligere og tidligere. Menarchealderen for pigerne i nærværende materiale er gennemsnitligt $13^1/_4$ år målt i kronologisk alder og $12^3/_4$ år målt i skeletalder. Forskellen på $^1/_2$ år skyldes det forhold, at det danske materiale skeletmæssigt er retarderet med ca. $^1/_2$ år i forhold til Brush Foundation materialet.

Der er signifikant større korrelation mellem skeletalder og menarchealder end mellem kronologisk alder og menarchealder.

Kapitel IX omhandler mammaudviklingen. Den begynder for nærværende materiales piger gennemsnitligt ved en kronologisk alder på 10,8 år og ved en skeletalder på 10,2 år. Man finder også for mammaudviklingens vedkommende en tendens til større afhængighed af skeletalder end af kronologisk alder, men forskellen er ikke signifikant.

Kapitel X omhandler pubesudviklingen. For pigernes vedkommende begynder den gennemsnitligt ved en kronologisk alder på 11,6 år og ved en skeletalder på 11,0 år. For drengenes vedkommende finder man for nærværende materiale, at pubesudviklingen gennemsnitligt begynder ved en kronologisk alder på 12,8 år og ved en skeletalder på 12,4 år. For såvel piger som drenge finder man en signifikant større korrelation mellem pubesudvikling og skeletalder end mellem pubesudvikling og kronologisk alder.

I *kapitel XI* fremlægges resultaterne af målinger af testes. Tilvæksten er størst i 11–14 års alderen. For denne aldersgruppes vedkommende gælder det, at der er signifikant større korrelation mellem testes' vækst og skeletalder end mellem testes' vækst og kronologisk alder.

Af *kapitel XII* fremgår, at væksten af penis især foregår i 12–15 års alderen. Der ses tendens til større korrelation mellem vækst af penis og skeletalder end mellem vækst af penis og kronologisk alder, men forskellen er ikke signifikant.

Af *kapitel XIII* fremgår, at stemmen hos drengene i nærværende materiale går i overgang ved en gennemsnitlig kronologisk alder på $15\,^1/_2$ år og ved skeletalderen 15 år. Moustache fremkommer gennemsnitligt ved den kronologiske alder $14^1/_4$ år og ved skeletalderen $13^3/_4$ år. Der er signifikant større korrelation mellem stemmens overgang og skeletalder end mellem stemmens overgang og kronologisk alder. Der er en stærk tendens til, at fremkomsten af moustache er nærmere korreleret til skeletalder end til kronologisk alder, men der påvises ingen signifikans.

I *kapitel XIV* gøres først rede for forskellige faktorer som arv, ernæring, sygdom og hormonproduktion, der kan påvirke udviklingen, derunder skeletudviklingen. I nærværende undersøgelse har man sat skeletudviklingen i relation til forsørgerens erhverv, hans ansatte skattepligtige indkomst, til boligens størrelse samt til, hvorvidt moderen havde udeerhverv eller ej. Med faldende erhvervsmæssig status påviser man en signifikant større procentdel børn med retarderet knogleudvikling. Der findes også en tendens til, at procenten af retarderede stiger med faldende indkomst, men der påvises ingen signifikans.

Man finder videre, at knogleudviklin-

for skeletaldre, bedømt efter Tanner & Whitehouse's system. De er identiske for de lave aldre, men fra det fyldte 13 år for drengenes vedkommende og det fyldte 11 år for pigernes vedkommende er der foretaget en ny vurdering fordi vurderingen af håndrodsknoglerne var behæftet med visse vanskeligheder

Efter Greulich & Pyle's atlas er drengene i nærværende materiale retarderet med gennemsnitligt 5 9 måneder i forhold til materialet, der ligger til grund for atlas, og pigerne med gennemsnitligt 5 2 måneder

Bedømt efter Tanner & Whitehouse's metode er nærværende materiale avanceret med gennemsnitligt 2 3 måneder i forhold til de af Tanner & Whitehouse undersøgte børn. Det gælder for både drenge og piger

Spredningen på skeletalderbestemmelsen foretaget efter Greulich & Pyle's atlas, er 12 4 måneder for drenge og 11,5 måneder for piger og efter Tanner & Whitehouse's metode 13 0 måneder for drenge og 10 8 måneder for piger Tallene angiver gennemsnit for alle de undersøgte aldersgrupper Spredningen omfatter biologisk variation og målefejl. Den fundne spredning er af samme størrelsesorden som i tidligere arbejder

Den variable fejl på skeletalderbestemmelsen efter Greulich & Pyle's atlas i nærværende undersøgelse er 3–4 måneder og af samme størrelsesorden som hos andre undersøgere.

I det videre arbejde har man foretrukket at anvende resultaterne af skeletalderbestemmelsen foretaget efter Greulich & Pyle's atlas, dels fordi det er en simpel og hurtig metode at indøve og anvende dels fordi den i nærværende undersøgelse har vist sig at være lige så nøjagtig som Tanner & Whitehouse's system.

I *kapitlerne VII–VIII* har man søgt at vurdere i hvor høj grad skeletalderen kan anvendes som mål for den biologiske udvikling, idet man har sammenholdt den med andre udviklingskriterier som højde, indtræden af menarche, mamma og pubesudvikling m. m..

List of Supplements to Acta Paediatrica Scandinavica

(A list of earlier supplements can be obtained from Almqvist & Wiksells Boktryckeri AB, Uppsala, Sweden without charge.)

131. Mellbin, Tore. The Children of Swedish Nomad Lapps. A Study of their Health, Growth and Development. Sw kr 25.— 1962
132. Börjeson, Mats, Overweight Children. Sw kr. 25.— 1962
133. Lundström, Rolf, Rubella during Pregnancy. A Follow-up Study of Children Born after an Epidemic of Rubella in Sweden 1951 with Additional Investigations on Prophylaxis and Treatment of Maternal Rubella. Sw kr. 25.— 1962
134. Möller, Tage, Shunt Operations in Morbus Caeruleus. Results in 161 Cases and Clinical Follow-up. Sw kr 25.— 1962
135. *In Honour of Curt Gyllenswärd at his Retirement from the Professorship of Paediatrics at Karolinska Institutet.* June 30, 1962. Sw kr 25.— 1962
136. Bille, Bo, Migraine in School Children. A study of the incidence and short-term prognosis, and a clinical, psychological and electroencephalographic comparison between children with migraine and matched controls. Sw. kr 25.— 1962
137. Hansen, A. E., Stewart, R. A., Hughes, G. and Söderhjelm, L., The Relation of Linoleic Acid to Infant Feeding. A Review. Sw kr 25.— 1962
138. Wallgren, Eric Ivar. Pulmonary and Renal Circulation in Children with Patent Ductus Arteriosus. Pre- and Postoperative Studies of Thirty-four Cases. Sw kr 25.— 1962
139. Westin, Björn, Nyberg, Rune, Miller, James A., Jr. and Wedenberg, Erik, Hypothermia and Transfusion with Oxygenated Blood in the Treatment of Asphyxia Neonatorum. Sw kr 30.— 1962
140. *The Proceedings of the Thirteenth Northern Paediatric Congress.* Copenhagen, 1961. Edited by E. Winge Flensborg. Sw. kr. 30.— 1963
141. Wass-Häckert, Ole and Dencker, Märta, Late Prognosis in Tuberculous Meningitis. A clinical, neurological, ophthalmological, otological, psychological, psychiatric, electroencephalographical, radiological and sociomedical study. Sw kr 25.— 1963
142. Sterner, Göran, Adenovirus Infection in Childhood. An epidemiological and clinical survey among Swedish children. Sw kr. 25.— 1963
143. Lundberg, Åke, Paroxysmal Tachycardia in Infancy. A Clinical and Experimental Study. Sw. kr 25.— 1963
144. Sterky, Göran, Diabetic Schoolchildren. Sw kr 30.— 1963
145. Walsh, S. Zoe, Evolution of the Electrocardiogram of Healthy Premature Infants During the First Year of Life. Sw kr 20.— 1963
146. *In Honour of Sture Siwe at his Retirement from the Professorship of Paediatrics at the University of Lund, June 30, 1963.* Sw kr. 25.— 1963
147. Åstrand, P.-O., Engström, L., Eriksson, B. O., Karlberg, P., Nylander, I., Saltin, B. and Thorén, C., Girl Swimmers. With Special Reference to Respiratory and Circulatory Adaptation and Gynaecological and Psychiatric Aspects. Sw kr 25.— 1963
148. Berven, Hans, The Physical Working Capacity of Healthy Children. Seasonal Variations and Effect of Ultraviolet Irradiation and Vitamin-D Supply. Sw kr 20.— 1963
149. Valaes, Theos, Bilirubin Distribution and Dynamics of Bilirubin Removal by Exchange Transfusion. Sw kr 25.— 1963
150. Moe, Peter Johan, Iron Requirements in Infancy. Longitudinal studies of iron requirements during the first year of life. Sw kr 25.— 1963
151. *Preventive Paediatrics in the Undergraduate Curriculum. Symposium Held with the Collaboration of the World Health Organization of the X International Congress of Paediatrics.* Lisbon, 1962. Edited by Bo Vahlquist. Sw kr 15.— 1963
152. Hjern, Bo and Nylander, Ingvar. Acute Head Injuries in Children. Traumatology, Therapy and Prognosis. Sw. kr 15.— 1964
153. Thorén, Claes, Cardiomyopathy in Friedreich's Ataxia. With Studies of Cardiovascular and Respiratory Function. Sw kr 25.— 1964
154. Hall, Bertil, Mongolism in Newborns. A Clinical and Cytogenetic Study. Sw. kr 30.— 1964
155. Engström, Inga, Respiratory Studies in Children. XI. Mechanics of Breathing, Lung Volumes and Ventilatory Capacity in Asthmatic Children from Attack to Symptom-free Status. Sw. kr. 25.— 1964
156. *Nils Rosén von Rosenstein and his Textbook on Paediatrics.* Edited by Bo Vahlquist and Arvid Wallgren. Sw. kr. 25.— 1964
157. Brante, G., Kaijser, K. and Öckerman, P. A., Glycogenosis Type 1 (Lack of Glucose-6-Phosphatase) in Four Siblings. Sw. kr. 15.— 1964
158. Aarskog, Dagfinn, Cortisol in the Newborn Infant. Sw. kr. 25.— 1965
159. *Proceedings of the Fourteenth Northern Paediatric Congress.* Stockholm. 1964. Edited by Y. Larsson. Sw kr. 25.— 1965
160. Öckerman, P. A., Glycogen Storage Disease in Sweden. S kr. 25.— 1965
161. Peltonen, T. and Hirvonen, L., Experimental Studies on Fetal and Neonatal Circulation. Sw. kr. 20.— 1965
162. Lundmark, Karl Martin, Bone Marrow Cell Proliferation in Health and in Haematological Disease during Childhood. Sw. kr 25.— 1966
163. *Newborn Infant Cry.* Edited by John Lind. Sw. kr 30.— 1965
164. Böttiger, Margareta, Studies on Immunization with Inactivated and Live Poliovirus Vaccines. Sw kr. 20.— 1966
165. Glauser, E. M., Cook, C. D., Harris, G. B. C. and Shaw, J. E., Bronchiectasis: A Review of 187 Cases in Children with Follow-up Pulmonary Function Studies in 58. Sw kr 20.— 1966
166. Laaksonen, Anna-Liisa, A Prognostic Study of Juvenile Rheumatoid Arthritis. Analysis of 544 Cases. Sw kr. 35.— 1966
167. Iversen, Torben, Leukaemia in Infancy and Childhood. A Material of 570 Danish Cases. Sw kr. 30.— 1966
168. Trojaborg, W. Focal Spike Discharges in Children, a Longitudinal Study. Sw kr 25.— 1966
169. Dahl, Matti, Intracardiac Phonocardiography of the Right Heart in Children. Sw kr 30.— 1966
170. Bellman, Margit, Studies on Encopresis. Sw. kr 30.— 1966
171. Olding, Lars, Bacterial Infection in Cases of Perinatal Death. A Morphological and bacteriological study based on 264 autopsies. Sw kr 20.— 1966
172. *Festschrift in Memory of Constantin Chorenis.* Sw. kr 25.— 1967
173. Walsh, S. Zoe, The Esophageal Electrocardiogram during the *First Week of Life.* Sw. kr 25.— 1967
174. Petersson, Per Owe, Atrial Septal Defect of Secundum type. A clinical study before and after operation with special reference to haemodynamic function. Sw kr 25.— 1967

CONTENTS

INTRODUCTION

This work was originally started with the purpose of investigating the incidence of arterial bronchopulmonary anastomoses in the normal human infant lung and in congenital heart disease. These anastomoses are of particular interest in cardiovascular malformations, since the anastomoses — at least in conditions with reduced pulmonary arterial flow — serve as a shunt between the systemic and pulmonary circulations (10 22, 28, 34, 50 51).

During the course of the study it became evident, however that the significance of the arterial bronchopulmonary anastomoses could be better understood if the study was extended to include other aberrations from the basic arterial pattern of the lung, such as pulmobronchial arteries and bronchopulmonary arteries.

Transposition of the great arteries was the first type of congenital heart disease chosen for investigation. This malformation is incompatible with life unless the anatomic conditions permit mixing of the systemic and pulmonary blood flow In the absence of anomalies of venous return and cardiac septal defects, these infants largely depend upon the shunting capacities of the foramen ovale and the ductus arteriosus. This part of the study was undertaken to find out *a)* whether isolated transposition is associated with any particular type of intrapulmonary arterial pattern which might offer an auxiliary shunt, or crossing-over between the systemic and pulmonary circulations otherwise connected in parallell and *b)* whether, in transposition, the intrapulmonary arterial pattern is influenced by the presence of interventricular septum defect.

Arterial Bronchopulmonary Anastomoses, Pulmobronchial Arteries and Bronchial-Artery Supply of the Pulmonary Parenchyma in Infancy and Childhood

Normal. The discovery of the arterial bronchopulmonary anastomoses has been attributed to Ruysch, who on the basis of injection studies gave the following description, in 1696

"Variis autem locis haec arteria bronchialis anastomosibus associatur ramusculis minutissimis arteriae pulmonalis. Repleta enim arteria pulmonali ceracea materia illico quoque repleti conspiciuntur ramuli arteriae bronchialis nullusque dubito, quin hoc vice versa quoque fiat, quamvis id nunquam tentarim* (45)

Since the original description there has been a great deal of controversy concerning the incidence of arterial bronchopulmonary anastomoses in the normal human lung. Many workers claim to have demonstrated their existence (20, 23 4, 27—31 52) others have denied the normal occurrence of any precapillary communication between the bronchial and pulmonary arterial systems (7 13, 42, 47 51 58) The methods employed in these studies of the arterial bronchopulmonary anastomoses have been the corrosion cast technique (20 24, 29) angiography (7 13 20, 29 42, 47 58) microangiography (30, 31 51) and serial sectioning (13 28 29 52) Most of these studies were probably performed on adult material the ages of the subjects were usually not given.

The first report with special reference to the developing lung was presented by Küttner in 1878 (26) Using injection and corrosion cast techniques, he studied the human pulmonary arterial pattern in the late fetal period and in the newborn. He reported the frequent occurrence of subpleural anastomoses between bronchial and pulmonary arteries but does not seem to have noticed any intrapulmonary arterial anastomoses. Küttner observed, however, that branches from the pulmonary artery contribute to the arterial supply of the bronchi. He also recognized that the bronchial arteries of the fetus and newborn supply small areas of the pulmonary parenchyma proper in addition to the bronchial structures

Using injection techniques and dissection, Zuckerkandl in 1883 (59) confirmed the findings of Küttner concerning the subpleural anastomoses between bronchial and pulmonary arteries Zuckerkandl, however also demonstrated intrapulmonary ("tief liegenden") arterial bronchopulmonary anastomoses of the end-to-side and the end-to-end type. He further includes in the concept of anastomoses the *rami bronchiales arteriae pulmonalis* i.e. branches from the pulmonary artery supplying the bronchial tree. These various types of anastomoses, ac

* In many places the bronchial artery is connected as anastomoses with small branches of the pulmonary artery For when the pulmonary artery is injected with wax, branches of the bronchial artery are also filled no doubt the opposite (filling of the pulmonary artery by injection of the bronchial arteries) would also take place, although I have not yet tried so.

Arterial Bronchopulmonary Anastomoses, Pulmobronchial Arteries and Bronchial-Artery Supply of the Pulmonary Parenchyma in Infancy and Childhood

Normal The discovery of the arterial bronchopulmonary anastomoses has been attributed to Ruysch, who on the basis of injection studies gave the following description, in 1696

Variis autem locis haec arteria bronchialis anastomosibus associantur ramusculis minutissimis arteriae pulmonalis. Repleta enim arteria pulmonali ceracea materia illico quoque repleti conspiciuntur ramuli arteriae bronchialis nullusque dubito, quin hoc vice versa quoque fiat, quamvis id nunquam tentarim* (45)

Since the *original* description there has been a great deal of controversy concerning the incidence of arterial bronchopulmonary anastomoses in the normal human lung. Many workers claim to have demonstrated their existence (20 23 24, 27—31 52) others have denied the normal occurrence of any precapillary communication between the bronchial and pulmonary arterial systems (7 13 42, 47 51 58) The methods employed in these studies of the arterial bronchopulmonary anastomoses have been the corrosion cast technique (20 24, 29) angiography (7 13 20, 29 42, 47 58) microangiography (30 31 51) and serial sectioning (13 28, 29 52) Most of these studies were probably performed on adult material the ages of the subjects were usually not given.

The first report with special reference to the developing lung was presented by Küttner in 1878 (26) Using injection and corrosion cast techniques, he studied the human pulmonary arterial pattern in the late fetal period and in the newborn. He reported the frequent occurrence of subpleural anastomoses between bronchial and pulmonary arteries but does not seem to have noticed any intrapulmonary arterial anastomoses. Küttner observed, however that branches from the pulmonary artery contribute to the arterial supply of the bronchi. He also recognized that the bronchial arteries of the fetus and newborn supply small areas of the pulmonary parenchyma proper *in* addition to the bronchial structures.

Using injection techniques and dissection, Zuckerkandl in 1883 (59) confirmed the findings of Küttner concerning the subpleural anastomoses between bronchial and pulmonary arteries. Zuckerkandl, however also demonstrated intrapulmonary ("tief liegenden) arterial bronchopulmonary anastomoses of the end-to-side and the end-to-end type. He further includes in the concept of anastomosis the *vasa bronchiales arteriae pulmonalis* i.e. branches from the pulmonary artery supplying the bronchial tree. These various types of anastomoses, ac

* In many places the bronchial artery is connected by anastomoses with small branches of the pulmonary artery For when the pulmonary artery is injected with wax, branches of the bronchial artery are also filled no doubt the opposite (filling of the pulmonary artery by injection of the bronchial arteries) would also take place, although I have not yet tried so

cording to Zuckerkandl, may reach a diameter of 500 μ in the human lung

Konaschko in 1926 (25) made corrosion casts of the pulmonary and bronchial arteries of human infants newborn to 1 year of age. Without stating their frequency Konaschko reported the occurrence of intrapulmonary ("tiefliegenden") arterial bronchopulmonary anastomoses of the end to-side and of the end to-end type. He also observed subpleural end to-end anastomoses between bronchial and pulmonary arteries. These anastomoses were found particularly at the mediastinal aspect of the lung, less frequently in the diaphragmatic and costal areas The diameter of the subpleural anastomoses, according to Konaschko varies between 0 3 and 1 mm. Konaschko also recognized that the bronchial arteries normally supply small areas of the pulmonary parenchyma proper

Arterial bronchopulmonary anastomoses were found in the lungs of newborn and older infants by Verloop in 1948 (53) and by Weibel, in 1959 (57) who both used serial sectioning, and by Marchand Gilroy & Wilson, in 1950 (37) who used the corrosion cast technique and angiography these observations were, however based on very small series. Verloop described deep-lying and superficial anastomoses, the former being the more frequent, but remarked that these anastomoses are rare in the human neonatal lung (53) According to Weibel, the arterial bronchopulmonary anastomoses do not occur regularly but haphazardly and infrequently in the human neonatal lung (57) Marchand, Gilroy & Wilson were unable to demonstrate such anastomoses by the corrosion cast technique in the human neonatal lung Anastomoses were found, however with the same technique in the lungs of a two-year-old human infant, who had died of meningitis and whose lungs were considered normal In angiographic studies by the same workers on lung specimens from newborn infants, contrast medium passed from the bronchial to the pulmonary arteries indicating precapillary communications between the two arterial systems of the lung (37)

Tobin, in 1952 (50) made injection studies of the arterial pattern of human lungs from subjects of varying age. Arterial bronchopulmonary anastomoses were found though not consistently in the lungs of newborn and older infants, but their relative frequencies in various age groups were not analyzed

Liebow et. al. (1959) concluded from corrosion casts of the pulmonary vasculature that "localized congenital communications between the systemic and pulmonary arteries in the absence of heart disease occur with extreme rarity (33)

No arterial bronchopulmonary anastomoses were reported by Marini & Camarri, who employed serial sectioning in their study on the vasculature of the human fetal lung (38 39)

Wagenvoort, Heath & Edwards, in 1964, stated that arterial bronchopulmonary anastomoses occur "relatively often and close together in the lungs of fetuses and infants After the age of two years according to the same investigators, these anastomoses are rare in the absence of cardiac or pulmonary disease (54)

In a recent study on the vasculature of human "perinatal lungs Wagenvoort & Wagenvoort using serial sectioning demonstrated only occasional arterial bronchopulmonary anastomoses More frequent than the anastomoses were pulmobronchial

arteries (bronchial arteries originating from pulmonary arteries) Focal bronchial artery supply of the pulmonary parenchyma proper was demonstrated in most specimens from the late fetal and immediate neonatal period. This feature was particularly prominent in immature subjects and was not encountered in infants older than 6 weeks (55 56)

Transposition of the g eat arteries Previous structural investigations on the vasculature of the infant lung in transposition of the great arteries have largely been concerned with the effects of pulmonary hypertension on the pulmonary arterial bed. Medial hypertrophy in muscular pulmonary arteries, intimal proliferation, thrombotic and plexiform lesions have been reported to occur from the age of 1—2 months, though particularly in cases with coexisting interventricular septum defect (18, 19 43, 54) Increased bronchial-artery supply of the lungs, however has been reported in infants and older subjects with transposition of the great arteries (1 2, 10—12, 14, 15 17 19 28) but the intrapulmonary course of the bronchial arteries was not analyzed in detail, nor were the findings correlated to the presence of associated cardiac defects.

Microangiographic technique has not previously been applied to the study of the pulmonary vasculature in transposition of the great arteries.

MATERIAL

The material consisted of autopsy lung specimens from

I) 37 neonatal (immature, premature and full-term) infants without evidence of cardiovascular malformation or abnormal pulmonary histiogenesis,

II) 15 infants, ranging in age from 3 weeks to 4 years and 7 months, all without evidence of malformations involving the respiratory or cardiovascular systems and without evidence of chronic pulmonary disease,

III) 10 infants, ranging in age from 5 hours to 1 month and 24 days with transposition of the great arteries as an isolated cardiovascular malformation and

IV) 7 infants, ranging in age from 4 days to 4 months and 27 days, with transposition of the great arteries associated with interventricular septum defect.

In the majority of the subjects, including all subjects in series III and IV both lungs were available for microangiographic examination In the remaining subjects only one lung was available, either because of diagnostic procedures or because of failure of injection. In series I which originally consisted of 41 subjects, 4 had to be excluded because of incomplete filling of the lung specimen or extensive vascular ruptures.

The series of normal neonatal autopsy subjects (I) was selected, in order to get a fairly uniform representation of different gestational age groups. The remaining series (II—IV) were collected consecutively

A survey of the material is given in Table 1

Table 1 *Survey of the material*

Diagnosis, age	Number of subjects	Lungs injected		Number of stereoscopic pairs of microangiograms per subject, mean	Number of blocks serially sectioned per subject, mean
		one	both		
Normal Late fetal and neonatal period Birth weight range 450—4250 g	37	7	30	6	13
Normal Infancy and early childhood	15	5	10	13	12
Transposition of the great arteries. Early infancy	10		10	11	9
Transposition of the great arteries + interventricular septum defect. Early infancy	7		7	9	5
Total	69	12	57		

The pulmonary or bronchial arteries were injected with 7.5 per cent tap water (pH 6.4) suspension of fine barium sulphate (Micropaque ® Damancy & Co). This contrast medium, which has a particle diameter of 5—6 μ (21), reaches the capillary bed of the lung.

For the injection of the *pulmonary arterial system* one or both lungs (including the bronchi and the trachea) were removed at autopsy and separated from the heart. The injection was made into the pulmonary arteries of each lung or into the pulmonary trunk after ligation of the ductus arteriosus — when not anatomically closed. The pulmonary veins were left open. The injection pressure was recorded and kept around 60 mm Hg (40—80 mm Hg) non-pulsatile, in specimens from normal fetuses and infants (I, II). In specimens from both groups of infants with transposition (III, IV) the pulmonary arteries were injected at a pressure of about 100 mm Hg (80—120 mm Hg). The lungs were unexpanded and in atmospheric conditions during the injection procedure. Irregular capillary filling in subpleural pulmonary lobules was usually visible within the first minute of injection. Capillary filling rapidly increased as did the volume of the injected lung. After a few minutes, the lung appeared to be more or less saturated with contrast the consumption of contrast decreased, but did not cease altogether. I most instances, a slight leakage of contrast through the open pulmonary veins was observed during the injection.

For the filling of the *bronchial arterial system* the thoracic viscera were removed *en bloc* without opening the oesophagus, the trachea or the bronchi. The heart was removed and the following arteries were ligated the ascending aorta, the pulmonary trunk, the ductus arteriosus (when not anatomically closed) the common carotid, subclavian and intercostal arteries. The pulmonary veins were left open. A cannula was tied into the thoracic aorta with its tip slightly above the level of the diaphragm. I jection was made at a pressure of about 100 mm Hg (80—120 mm Hg) throughout the series. Contrast leakage through small mediastinal arteries opened when removing the specimen was prevented by clamping and ligation and could, as a rule, be reduced to a minimum. Filling of pleural branches of the bronchial arteries was usually visible within a few minutes at the mediastinal aspect of the lung and at the interlobar fissures. In some specimens incomplete capillary filling of the pulmonary parenchyma, visible from the pleural surface, indicated either transmission of contrast from one arterial system to the other or the presence of direct systemic-artery supply of the pulmonary parenchyma. A light flow from the open pulmonary veins was observed in some specimens.

A few lung specimens from infants with transposition were double-injected first *via* the bronchial arteries and thereafter *via* the pulmonary arteries (III, IV).

The injection time was generally at least 30 minutes (60 minutes in the double-injected specimens).

MATERIAL

The material consisted of autopsy lung specimens from

I) 37 neonatal (immature, premature and full term) infants without evidence of cardiovascular malformation or abnormal pulmonary histiogenesis

II) 15 infants, ranging in age from 3 weeks to 4 years and 7 months, all without evidence of malformations involving the respiratory or cardiovascular systems and without evidence of chronic pulmonary disease

III) 10 infants, ranging in age from 5 hours to 1 month and 24 days, with transposition of the great arteries as an isolated cardiovascular malformation, and

IV) 7 infants, ranging in age from 4 days to 4 months and 27 days, with transposition of the great arteries associated with interventricular septum defect.

In the majority of the subjects, including all subjects in series III and IV both lungs were available for microangiographic examination In the remaining subjects only one lung was available, either because of diagnostic procedures or because of failure of injection. In series I, which originally consisted of 41 subjects, 4 had to be excluded because of incomplete filling of the lung specimen or extensive vascular ruptures

The series of normal neonatal autopsy subjects (I) was selected in order to get a fairly uniform representation of different gestational age groups The remaining series (II—IV) were collected consecutively

A survey of the material is given in Table 1

Table 1 *Survey of the material*

The pulmonary or bronchial arteries were injected with 75 per cent tap water (pH 6.4) suspension of fine barium sulphate (Micropaque® Damancy & Co). This contrast medium, which has a particle diameter of 5—6 μ (21) reaches the capillary bed of the lung.

For the injection of the *pulmonary arterial system* one or both lungs (including the bronchi and the trachea) were removed at autopsy and separated from the heart. The injection was made into the pulmonary arteries of each lung or into the pulmonary trunk after ligation of the ductus arteriosus — when not anatomically closed. The pulmonary veins were left open. The injection pressure was recorded and kept around 60 mm Hg (40—80 mm Hg) non-pulsatile, in specimens from normal fetuses and infants (I, II). In specimens from both groups of infants with transposition (III, IV) the pulmonary arteries were injected at a pressure of about 100 mm Hg (80—120 mm Hg). The lungs were unexpanded and in atmospheric conditions during the injection procedure. Irregular capillary filling in subpleural pulmonary lobules was usually visible within the first minute of injection. Capillary filling rapidly increased as did the volume of the injected lung. After a few minutes, the lung appeared to be more or less saturated with contrast the consumption of contrast decreased, but did not cease altogether. In most instances, a slight leakage of contrast through the open pulmonary veins was observed during the injection.

For the filling of the *bronchial arterial system* the thoracic viscera were removed *en bloc* without opening the oesophagus, the trachea or the bronchi. The heart was removed and the following arteries were ligated the ascending aorta, the pulmonary trunk, the ductus arteriosus (when not anatomically closed) the common carotid, subclavian and intercostal arteries. The pulmonary veins were left open. A cannula was tied into the thoracic aorta with its tip slightly above the level of the diaphragm. Injection was made at a pressure of about 100 mm Hg (80—120 mm Hg) throughout the series. Contrast leakage through small mediastinal arteries opened when removing the specimen was prevented by clamping and ligation and could, as a rule, be reduced to a minimum. Filling of pleural branches of the bronchial arteries was usually visible within a few minutes at the mediastinal aspect of the lung and at the interlobar fissures. In some specimens incomplete capillary filling of the pulmonary parenchyma, visible from the pleural surface, indicated either transmission of contrast from one arterial system to the other or the presence of direct systemic-artery supply of the pulmonary parenchyma. A slight flow from the open pulmonary veins was observed in some specimens.

A few lung specimens from infants with transposition were double-injected first via the bronchial arteries and thereafter via the pulmonary arteries (III, IV).

The injection time was generally at least 30 minutes (60 minutes in the double-injected specimens).

After injection, the filling was checked in survey radiograms of the entire specimen. The injected lungs were fixed in neutral formalin for at least 4 days. Frontal slices of the lungs 2—3 mm thick, were then radiographed and representative specimens were taken from all lobes of the lungs including the hilus. Regions with evidence of transmission of contrast from one arterial system to the other were particularly looked for and selected for microangiography. The selected specimens were embedded in a mixture of 4/5 Histowax® (Matheson Coleman & Bell) and 1/5 yellow bees wax. This type of embedding gives to the specimen a consistency suitable for the subsequent cutting in slices 1000—2000 μ thick.

In the following microangiographic procedure, the exposure was made on Kodak Maximum Resolution Plates, which have a resolution better than 1000 lines per mm. A Matchlett OEG 50 X-ray tube was used (40 kV 8 mA) with a focus-to-film distance of 90 cm and an exposure time of 3 hours. The specimen was in contact with the film during the exposure. A stereo-pair of microangiograms was produced from each block by moving the specimen laterally on the base plate between the exposures. A displacement of the specimen of 15 cm, corresponding to an angle of 9° between the two exposures, was found to give an acceptable threedimensional image. An average of 6—13 pairs of microangiograms measuring about 3×4—6 cm were produced in each subject (Table 1).

The microangiograms were scrutinized in a stereo-microscope and areas of particular interest were cut out from the blocks and re-embedded in paraffin for histologic examination. Serial sections were cut from all areas with evidence of arterial broncho-pulmonary anastomoses or pulmobronchial arteries in the microangiograms, and from other areas with an unusual appearance. The histologic sections, 6—7 μ thick, were stained with Verhoeff's or Weigert's elastic tissue stain and counterstained with van Gieson stain. An average of 5—13 blocks were serially sectioned in each subject (Table 1).

Comment

The injection pressure levels used in this study were chosen according to the following principles:

a) they should approximate the intra-vitam levels, and

b) they should be kept constant throughout the series in order to permit a comparison of vascular diameters in corresponding areas of the injected specimens.

The simultaneous fulfillment of both these principles is obviously difficult in a material consisting of immature, premature and full-term fetuses, neonatal and older normal infants and children as well as neonatal and older infants with transposition of the great arteries. The pressure of 60 mm Hg (40—80 mm Hg) corresponds rather well to the normal pressure in the pulmonary artery in the fetal and immediate neonatal period, but it is obviously too high for older infants and children. The pressure of 100 mm Hg (80—120 mm Hg) used for the injection of the pulmonary arterial system in transposition of the great arteries was chosen to match the pulmonary hypertension regularly present in these infants (49). The same pressure of 100 mm Hg (80—120 mm Hg) used throughout the series for the injection of the bronchial arterial system approximates the intra-vitam level in normal infancy and childhood as

well as in transposition of the great arteries. The pressure, however is too high for the late fetal period. Consequently the choice of injection pressure levels in the present study is the result of a compromise between the two principles outlined above.

In the initial phase of the study a longer injection time was used ($\leq 2\frac{1}{2}$ hours) but since it became evident that the injection time could be considerably reduced without altering the degree of filling of the specimens (as checked in survey radiograms and in the microangiograms) the injection time was settled at 30 minutes. In a few fetal specimens the injection had to be discontinued earlier because of vascular ruptures. Shorter injection periods were not tested.

The microangiographic technique was introduced by Bohatyrtschuk (8) and later developed by Barclay (3 4) Bellman and Engström (5 6) made an analysis of the technique, examining in particular the factors that influence the quality of the radiogram, such as the type of film, contrast medium and X-ray equipment. The advantages of the stereo-microangiographic technique compared with other forms of injection methods, such as stain injection, corrosion cast technique and regular angiography were pointed out by Ljungqvist in his microangiographic study of the arterial pattern of the human kidney (35) Microangiography seems to be the best method for the purpose of the present study since it permits subsequent histologic examination of the specimens by serial sectioning — the only reliable way of morphologically demonstrating the existence of vascular anastomoses (48) With the combination of microangiographic and histologic techniques, the time-consuming procedure of "blind" serial sectioning is avoided.

Overlapping phenomena constitute an important challenge to the recognition of vascular communications in plain microangiograms. This difficulty is considerably reduced by the stereo-microangiographic technique, by which — as a rule — the vessels can be "separated" from one another and their spatial course can be followed. The distortion of the vascular pattern in the microangiographic image, due to varying vessel-to-film distance, can be disregarded owing to the wide focus-to-film distance (90 cm) The same holds for the small distortion of the vascular pattern due to the lateral movement of the specimen between the two exposures in the production of a stereoscopic pair of microangiograms. The re-embedding and subsequent histologic sectioning of selected areas of the radiographed blocks generally resulted in a slight shrinkage of the specimens with some further distortion of the vascular pattern, as compared to the microangiographic image. The injected vessels, however, could be recognized without difficulty in the histologic slides, and their course in the microangiograms could easily be related to the various levels in serial sections.

After injection, the filling was checked in survey radiograms of the entire specimen. The injected lungs were fixed in neutral formalin for at least 4 days Frontal slices of the lungs, 2—3 mm thick, were then radiographed and representative specimens were taken from *all* lobes of the lungs including the hilus Regions with evidence of transmission of contrast from one arterial system to the other were particularly looked for and selected for microangiography The selected specimens were embedded in a mixture of 4/5 Histowax® (Matheson Coleman & Bell) and 1/5 yellow bees wax. This type of embedding gives to the specimen a consistency suitable for the subsequent cutting in slices 1000—2000 μ thick.

In the following microangiographic procedure, the exposure was made on Kodak Maximum Resolution Plates, which have a resolution better than 1000 lines per mm. A Matchlett OEG 50 X ray tube was used (40 kV 8 mA) with a focus-to-film distance of 90 cm and an exposure time of 3 hours The specimen was in contact with the film during the exposure. A stereo-pair of microangiograms was produced from each block by moving the specimen laterally on the base plate between the exposures A displacement of the specimen of 15 cm, corresponding to an angle of 9° between the two exposures, was found to give an acceptable threedimensional image. An average of 6—13 pairs of microangiograms measuring about 3×4—6 cm were produced in each subject (Table 1)

The microangiograms were scrutinized in a stereo-microscope and areas of particular interest were cut out from the blocks and re-embedded in paraffin for histologic examination. Serial sections were cut from all areas with evidence of arterial broncho-pulmonary anastomoses or pulmobronchial arteries in the microangiograms, and from other areas with an unusual appearance. The histologic sections, 6—7 μ thick, were stained with Verhoeff's or Weigert's elastic tissue stain and counterstained with van Gieson stain. An average of 5—13 blocks were serially sectioned in each subject (Table 1)

Comment

The injection pressure levels used in this study were chosen according to the following principles

a) they should approximate the *intra-vitam* levels, and

b) they should be kept constant throughout the series in order to permit a comparison of vascular diameters in correspoding areas of the injected specimens.

The simultaneous fulfillment of both these principles is obviously difficult in a material consisting of immature, premature and full term fetuses, neonatal and older normal infants and children as well as neonatal and older infants with transposition of the great arteries. The pressure of 60 mm Hg (40—80 mm Hg) corresponds rather well to the normal pressure in the pulmonary artery in the fetal and immediate neonatal period but it is obviously too high for older infants and children. The pressure of 100 mm Hg (80—120 mm Hg) used for the injection of the pulmonary arterial system in transposition of the great arteries was chosen to match the pulmonary hypertension regularly present in these infants (49) The same pressure of 100 mm Hg (80—120 mm Hg) used throughout the series for the injection of the bronchial arterial system approximates the *intra-vitam* level in normal infancy and childhood as

well as in transposition of the great arteries. The pressure, however is too high for the late fetal period. Consequently the choice of injection pressure levels in the present study is the result of a compromise between the two principles outlined above.

In the initial phase of the study a longer injection time was used ($\leq 2\frac{1}{2}$ hours) but since it became evident that the injection time could be considerably reduced without altering the degree of filling of the specimens (as checked in survey radiograms and in the microangiograms) the injection time was settled at 30 minutes. In a few fetal specimens, the injection had to be discontinued earlier because of vascular ruptures. Shorter injection periods were not tested.

The microangiographic technique was introduced by Bohatyrtschuk (8) and later developed by Barclay (3, 4). Bellman and Engström (5, 6) made an analysis of the technique, examining in particular the factors that influence the quality of the radiogram, such as the type of film, contrast medium and X-ray equipment. The advantages of the stereo-microangiographic technique compared with other forms of injection methods such as stain injection, corrosion cast technique and regular angiography were pointed out by Ljungqvist in his microangiographic study of the arterial pattern of the human kidney (33). Microangiography seems to be the best method for the purpose of the present study since it permits subsequent histologic examination of the specimens by serial sectioning — the only reliable way of morphologically demonstrating the existence of vascular anastomoses (48). With the combination of microangiographic and histologic techniques, the time-consuming procedure of "blind" serial sectioning is avoided.

Overlapping phenomena constitute an important challenge to the recognition of vascular communications in plain microangiograms. This difficulty is considerably reduced by the stereo-microangiographic technique, by which — as a rule — the vessels can be "separated" from one another and their spatial course can be followed. The distortion of the vascular pattern in the microangiographic image, due to varying vessel-to-film distance, can be disregarded owing to the wide focus-to-film distance (90 cm). The same holds for the small distortion of the vascular pattern due to the lateral movement of the specimen between the two exposures in the production of a stereoscopic pair of microangiograms. The re-embedding and subsequent histologic sectioning of selected areas of the radiographed blocks generally resulted in a slight shrinkage of the specimens with some further distortion of the vascular pattern, as compared to the microangiographic image. The injected vessels, however, could be recognized without difficulty in the histologic slides, and their course in the microangiograms could easily be related to the various levels in serial sections.

RESULTS

Pulmonary arterial system

Basic pattern

Normal The branches of the pulmonary artery generally follow those of the bronchi The "medullary (circumhilar) zone of the lung, however is also normally supplied by numerous muscular lobular arteries arising more or less perpendicularly from the elastic pulmonary arteries These "abrupt branches are much narrower than their parent vessel and they are not accompanied by a bronchus at their point of origin After entering an adjacent lobulus, some of these branches can be seen to join an intralobular bronchus of corresponding size (I II)

A few pulmonary arterioles leave their lobules to supply either septal tissue or the pleura. These vessels run at the costal, basal and mediastinal aspects of the lung and at the interlobar fissures. Their diameter ranges from 25 to 75 μ in the late fetal — neonatal lung (I) and from 25 to 250 μ in infancy and early childhood (II) A few of these vessels form arterial bronchopulmonary anastomoses (see below)

Occasionally a pulmonary arteriole or a muscular pulmonary artery traverses the interlobular septum to ramify in an adjacent lobulus. This feature was encountered in a few specimens from normal late fetal — neonatal lungs (I) and in one specimen from a normal infant, age two year and eight months (II)

Transposition of the great arteries Deviation from the normal intrapulmonary arterial pattern was observed in all pulmonary artery injected lung specimens from infants with *isolated transposition* i.e. in six subjects. Two fairly distinct types of peripheral arterial pattern were recognized in the microangiograms and were arbitrarily denoted as Type I and Type II

Type I present in three subjects, is characterized by a rapid decrease in the diameter of the lobular pulmonary arteries at a level corresponding to the zone of transition of mural structure from predominantly elastic to predominantly muscular Peripherally to the funnel shaped narrowing, the pulmonary arteries branch into bundles of small muscular arteries of about equal size, some of which even slightly wider than their parent artery Many of these branches display focal narrowing through intimal cushions of endothelial and smooth-muscle cells.

In Type II present in the other three subjects there is a more gradual decrease in the diameter of the pulmonary arteries towards the periphery of the lung Deviation from the normal pattern is seen predominantly in the form of increased tortuosity of intralobular pulmonary arteries.

Abrupt muscular branches from elastic pulmonary arteries were about as frequent as in specimens from normal fetuses and infants and their frequency was unrelated to the Type I or the Type II patterns Particularly in specimens with Type I pattern many of the abrupt branches are narrowed shortly after their point of origin by intimal

cushions of endothelial and smooth-muscle cells. In three of the subjects with isolated transposition, the subdivisions of many of the abrupt branches from octopus-like bundles in one of these subjects the abnormal abrupt branches give rise to several pulmobronchial arteries (see below)

In two infants with isolated transposition (ages 10 days and 21 days, bronchial-artery injected specimens) *obliterated* muscular pulmonary arteries were encountered in areas also supplied by "bronchopulmonary arteries (see below) indicating that the arterial supply of these areas had been taken over by the bronchial arterial system.

A few pulmonary arterioles leave their lobules to supply either septal tissue or the pleura or to anastomose end-to-end with septal or pleural branches of the bronchial arteries (see below) The diameter of these "penetrating pulmonary arterioles ranges up to 125 μ (III)

In the series of seven infants with *transposition associated with interventricular septum d fect* the Type I of intralobular arterial pattern was not encountered. The microangiographic pattern of the pulmonary arterial system was essentially normal in two subjects. In three subjects there was increased tortuosity of intralobular pulmonary arteries, corresponding to the abovementioned Type II pattern. In the two remaining subjects the injection had been made into the bronchial arteries and a microangiographic analysis of the pulmonary arterial pattern was not possible.

Abrupt muscular branches from elastic pulmonary arteries were about as frequent and of the same type as in the normal infant lung

In one subject, a few pleural branches of the pulmonary artery were demonstrated at the costal and mediastinal aspects of the lung Their diameter ranges from 35 to 50 μ (IV)

Comment

The findings concerning the normal basic pattern of the pulmonary arterial system essentially agree with earlier observations. The "Type I pattern of intralobular pulmonary arteries, however demonstrated in infants with isolated transposition, does not seem to have been recognized previously The rapid, funnel-shaped decrease in the diameter of the intralobular pulmonary arteries in combination with the cellular intimal cushions of these arteries suggest a higher vascular resistance than normal or in the "Type II" pattern. This could be related to low survival time of individuals with Type I pattern compared with those with Type II pattern (III)

Tortuosity of intralobular pulmonary arteries — a prominent feature of the Type II pattern — is obviously not specifically related to transposition of the great arteries, since it has been observed in post-mortem angiograms from cases of pulmonary hypertension secondary to other forms of congenital heart disease (16, 46)

Pulmobronchial arteries

The term pulmobronchial arteries was recently suggested by Wagenvoort & Wagenvoort (55 56) to denote intrapulmonary bronchial arteries originating as branches of the pulmonary artery These structures, which appear to substitute for the "ordinary bronchial arteries along a few bronchi, were previously referred to as *rami pulmobronchiales* (9 23, 24) or *rami bronchiales arteriae pulmonalis* (59)

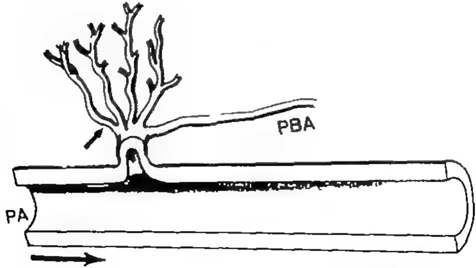
C Abnormal pulmobronchial artery (PBA) with *arrayed* ramifications to the pulmonary parenchyma proper (*small arrow*) Isolated transposition of the great arteries



D Abnormal pulmobronchial artery (PBA) originating as part of octopus-like ramifications (*small arrow*) of abrupt branch of the pulmonary artery (PA) Isolated transposition of the great arteries.

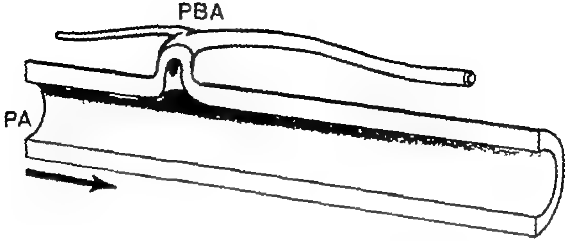


Fig 1 Diagrams showing various patterns of pulmobronchial arteries. Direction of flow in the pulmonary artery (PA) is indicated by *big arrows*

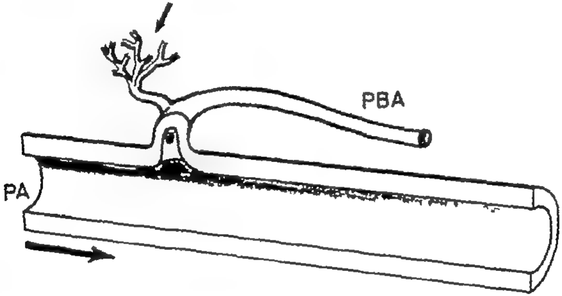
A. Normal pulmobronchial artery (PBA) with concurrent and recurrent branches.



B. Normal pulmobronchial artery (PBA) with concurrent branch and small ramifications to the pulmonary parenchyma proper (*small arrow*)

Normal Pulmobronchial arteries were demonstrated in small numbers in 9 of 37 subjects (24 per cent) in the study of the late fetal and neonatal lung Their diameter at their points of origin ranges from 25 to 100 μ (I) In the study of the pulmonary vasculature in infancy and early childhood, pulmobronchial arteries were demonstrated in 8 of 15 subjects (53 per cent) They are few in number and their diameter ranges from 50 to 330 μ (II)

After leaving their parent pulmonary artery the pulmobronchial arteries generally turn distally along the neighboring bronchus but they also send recurrent branches along the same bronchus (Fig 1 A) Small rami

the origin of an arterial vessel in the bronchial wall. Consequently there is a degree of uncertainty in the classification and counting of these structures, and the absolute figures given above for their incidence should be regarded as approximate. The relative frequencies, however are unlikely to have been systematically influenced.

The diameter of the pulmobronchial arteries were measured on injected vessels, which were often distended with contrast. Furthermore, the injection pressure was not uniform throughout the series (cf p. 15) The diameter values therefore cannot be regarded as a reliable index of functional capacity The findings in the present study concerning the size of the pulmobronchial arteries are, however, similar to the *findings* of Wagenvoort & Wagenvoort in their recent histological study on the vasculature of the human perinatal lung (56)

Pulmobronchial arteries with abnormal terminal ramifications in the pulmonary parenchyma — as demonstrated in isolated transposition — are sometimes *difficult to* distinguish from ordinary abrupt branches crossing the bronchial wall. An artery was classified as pulmobronchial, however, when it penetrated the cartilage level of the bronchial wall.

Bronchial arterial system

Basic pattern

Normal The bronchial arteries of the normal lung generally accompany the bronchi. Apart from their ramifications in the bronchial walls proper, they form the *vasa vasorum* of the major pulmonary vessels. They also supply septal tissue near the hilus as well as lymph nodes and peribronchial nerves. Pleural branches of the bronchial arteries occur regularly particularly near the hilus and at the interlobar fissures (I, II)

The inner diameter of the main bronchial arteries in the hilus of the late fetal and neonatal lung increases with fetal age and ranges from 125 to 300 μ (I) In infancy and early childhood (i.e. up to the age of four years and seven months) the diameter of the main bronchial arteries in the hilus of the lung ranges from 350 to 600 μ and does not seem to increase with age (II)

From the age of ten weeks, longitudinal intimal muscle cells are normally present in the bronchial arterial system, but the bronchial arteries are not uniformly involved. Particularly affected are branches forming the *vasa vasorum* of the main pulmonary vessels and those participating in arterial bronchopulmonary anastomoses (see below) Even among the "ordinary bronchial arteries, there is a variation within the same specimen, but as a rule the "Sperr artery structure of intrapulmonary and pleural bronchial arteries becomes more prominent with age. From the age of one year and four months some bronchial artery derived *vasa vasorum* of the pulmonary artery are completely obliterated by smooth muscle cells (II)

Transposition of the great arteries In transposition, with or without interventricular septum defect, the basic pattern of the bronchial arterial system does not deviate from the normal, i.e. the bronchial arteries largely follow the course of the bronchi, supplying the bronchial structures and lymph nodes. Pleural branches occur, as normally at the mediastinal aspect of the lung and at the interlobar fissures (III, IV)

fications to adjacent alveolar walls are occasionally observed These ramifications originate *proximal* to the point where the artery joins the bronchial wall (Fig 1 B) (I II)

The majority of the pulmobronchial arteries originate from elastic pulmonary arteries but occasionally they arise from intralobular pulmonary arterioles leaving their lobulus to join an adjacent prelobular bronchus This latter feature was observed only in the study of infancy and early childhood (II)

The mural structure of the pulmobronchial arteries, after they join the bronchial wall, cannot be distinguished from that of the ordinary bronchial arteries Like the latter they often accompany the peribronchial nerves. From the age of 11 weeks, they occasionally have a thin intimal layer of smooth muscle cells ("Sperr artery structure [24]) (I II)

Transposition of the great arteries In neonatal subjects with *isolated transposition* pulmobronchial arteries were demonstrated in three subjects (30 per cent) Their diameter at the point of origin ranges from 50 to 275 μ. They have the same mural structure as those of the normal neonatal lung

Divergence from the normal pattern was observed in the following aspects

a) Many of the pulmobronchial arteries deviated from the bronchial walls in their terminal course to ramify into alveolar capillaries The diameter of these deviating branches ranges up to 100 μ (Fig 1 C)

b) In one subject the pulmobronchial arteries were particularly frequent and some of them arose as part of octopus like ramifications of abrupt muscular branches from elastic pulmonary arteries (Fig 1 D) (III)

In the series of seven infants with *transposition associated with interventricular septum defect* a few pulmobronchial arteries were demonstrated in two subjects. Their diameter ranges from 75 to 200 μ and their course does not, as a rule, deviate from the normal pattern An exception is formed in one specimen by the presence of an anastomosis of side to-side type (diameter 75 μ) between a pulmobronchial artery and an adjacent "ordinary bronchial artery The mural structure of the pulmobronchial arteries is essentially the same as in the normal infant lung "Sperr artery structure of pulmobronchial arteries, however was not encountered in this part of the series (IV)

Comment

The microangiographic technique offers a fairly complete screening of the arterial systems of the lung but the points of origin of pulmobronchial arteries are sometimes hidden by close overlapping or by being present near or at the borderline between two slices of lung tissue A further source of error is the resemblance between pulmobronchial arteries with recurrent branches and arterial bronchopulmonary anastomoses. A pulmobronchial artery with recurrent branches can be distinguished from a true anastomosis, however since the recurrent branch gradually decreases in size towards the hilus whereas the opposite is true of a bronchial artery proximal to an anastomosis. This distinction may be very difficult even impossible, if the recurrent branch of a presumed pulmobronchial artery can be followed for only a short distance in the microangiograms or in the serial sections and its diameter remains constant in its visible portion. The wall structure *per se* is no clue to

the origin of an arterial vessel in the bronchial wall. Consequently there is a degree of uncertainty in the classification and counting of these structures and the absolute figures given above for their incidence should be regarded as approximate. The relative frequencies, however are unlikely to have been systematically influenced.

The diameter of the pulmobronchial arteries were measured on injected vessels, which were often distended with contrast. Furthermore, the injection pressure was not uniform throughout the series (cf p 13) The diameter values therefore cannot be regarded as a reliable index of functional capacity The findings in the present study concerning the size of the pulmobronchial arteries are, however similar to the findings of Wagenvoort & Wagenvoort in their recent histological study on the vasculature of the human perinatal lung (56)

Pulmobronchial arteries with abnormal terminal ramifications in the pulmonary parenchyma — as demonstrated in isolated transposition — are sometimes difficult to distinguish from ordinary abrupt branches crossing the bronchial wall. An artery was classified as pulmobronchial, however, when it penetrated the cartilage level of the bronchial wall.

Bronchial arterial system

Basic pattern

Normal The bronchial arteries of the normal lung generally accompany the bronchi. Apart from their ramifications in the bronchial walls proper they form the *vasa vasorum* of the major pulmonary vessels. They also supply septal tissue near the hilus as well as lymph nodes and peribronchial nerves Pleural branches of the bronchial arteries occur regularly particularly near the hilus and at the interlobar fissures (I, II)

The inner diameter of the main bronchial arteries in the hilus of the late fetal and neonatal lung increases with fetal age and ranges from 125 to 300 μ (I) In infancy and early childhood (i.e. up to the age of four years and seven months) the diameter of the main bronchial arteries in the hilus of the lung ranges from 350 to 600 μ and does not seem to increase with age (II)

From the age of ten weeks, longitudinal internal muscle cells are normally present in the bronchial arterial system, but the bronchial arteries are not uniformly involved Particularly affected are branches forming the *vasa vasorum* of the main pulmonary vessels and those participating in arterial bronchopulmonary anastomoses (see below) Even among the ordinary bronchial arteries, there is a variation within the same specimen, but as a rule the "Sperr artery structure of intrapulmonary and pleural bronchial arteries becomes more prominent with age. From the age of one year and four months some bronchial-artery derived *vasa vasorum* of the pulmonary artery are completely obliterated by smooth muscle cells (II)

Transposition of the great arteries In transposition, with or without interventricular septum defect, the basic pattern of the bronchial arterial system does not deviate from the normal, i.e. the bronchial arteries largely follow the course of the bronchi, supplying the bronchial structures and lymph nodes. Pleural branches occur as normally at the mediastinal aspect of the lung and at the interlobar fissures (III, IV)

In neonatal instances of *isolated transposition* the diameter range of the main bronchial arteries in the hilus of the lung *is increased to 375—1200 μ. In two subjects* with particularly wide and tortuous bronchial arteries, enlargement of the aortic orifices of the bronchial arteries was recorded at autopsy (III).

In infants with *transposition associated with interventricular septum defect* the diameter of the main bronchial arteries in the *hilus of the lung ranges from 175 to 475 μ*, i.e. within normal limits (IV). In neither *of the two series of infants with transposition* did the bronchial arteries display the mural structure of "Sperr"-arteries (III, IV).

Comment

The findings concerning the normal basic pattern of the bronchial arterial system are essentially in agreement with earlier observations by others. The "Sperr" artery structure of bronchial arteries, however, has not previously been recognized before the age of seven months (40). The functional claim on the bronchial arteries as oxygen carriers to the bronchial and peribronchial structures is most probably greater in the intrauterine state than in the postnatal *breathing lung*. Apart from the fact that the bronchial surface of the postnatal lung is in direct contact with air, the oxygen supply of the bronchial structures can — *at least in part* — be taken over by the pulmonary veins that drain *into the peribronchial* venous plexuses. The gradual development of "Sperr" artery structure in the bronchial arteries of the human postnatal lung can therefore be regarded as a process of involution or adaptation to extrauterine type of circulation. This theory, suggested by Verloop (53) and by Preto Parvis (44), is further supported by the findings of the present study concerning the size of the main bronchial arteries in the hilus of the lung. Whereas the diameter of these arteries increases with fetal age, it remains fairly constant during the first few years of postnatal life (II).

The increased size of the main bronchial arteries in cases of isolated transposition is obviously related to the extensive bronchial artery supply of the pulmonary parenchyma proper (III) (se below).

Bronchopulmonary arteries

The term "bronchopulmonary arteries", *which was recently suggested by Wagenvoort & Wagenvoort* (55, 56), indicates branches of the bronchial arteries which enter the pulmonary parenchyma proper to ramify into capillaries of alveolar walls.

Normal. Bronchopulmonary arteries were observed in all but one of the aorta injected specimens in the series of normal late fetal and neonatal lungs. Their diameter ranges up to 120 μ. They are particularly common in the "medullary" zone of the lung and are sometimes surrounded by a narrow sleeve of lymphoid tissue at their point of *entrance into the pulmonary parenchyma*. In places they substitute for the pulmonary artery along terminal bronchioles, and here their wall structure cannot be distinguished *from that of peripheral pulmonary arterioles* (I).

In the series of 15 subjects from infancy and early childhood, bronchopulmonary arteries (diameter range ≤ 200 μ) were demonstrated in 8 subjects varying in age from four weeks to four years and seven months. At the age of four weeks, the bronchopulmonary arteries have about the same frequency and extent *as in the normal neo-*

natal lung. From the age of six months, these arteries are only rarely encountered in the microangiograms. Particularly near their points of origin, some of the broncho-pulmonary arteries are thickwalled and narrow occasionally even obliterated by intimal layers of smooth muscle cells. This "Sperr" artery structure of bronchopulmonary arteries was not observed until the age of seven months (II)

In a few instances a pulmobronchial artery originates not far from the point where a bronchopulmonary artery deviates from the bronchial wall, indicating that the former substitutes for the latter by taking over the arterial supply of the bronchial wall. This feature was observed in the series of late fetal and neonatal lungs (I)

In places, contrast medium appeared to have passed from bronchopulmonary arteries to adjacent branches of the pulmonary artery though a common capillary network (I, II)

When present, the direct bronchial-artery supply of the pulmonary parenchyma (as bronchopulmonary arteries) consistently involved only a minute part of the normal late fetal and postnatal infant lung (I, II)

Transposition of the great arteries In isolated transposition there is prominent increase in the bronchial-artery supply of the pulmonary parenchyma. Although evident already in the neonatal period, this increase is still more pronounced in infants who survive the immediate neonatal period The bronchopulmonary arteries are numerous and they are derived from intrapulmonary as well as pleural branches of the bronchial arteries. Intrapulmonary bronchopulmonary arteries supply a large portion of the "medullary" zone of the lung The inner diameter of the bronchopulmonary arteries, at their points of entrance into the pulmonary parenchyma, ranges up to 200 μ. Their mural structure is the same as in the normal neonatal lung (III)

In the series of 7 infants with *transposition associated with interventricular septum defect* bronchopulmonary arteries were demonstrated in all aorta injected specimens and in one of the pulmonary artery injected specimens. Their number is within normal limits in three subjects and moderately increased in two subjects. Their diameter ranges up to 125 μ. As in the series of infants with isolated transposition, the majority of the bronchopulmonary arteries are derived from intrapulmonary bronchial arteries in the "medullary" zone of the lung, but a few small bronchopulmonary arteries (diameter range up to 50 μ) originate from pleural branches of the bronchial arteries. The mural structure of the bronchopulmonary arteries does not differ from the normal.

Transmission of contrast from bronchopulmonary arteries to adjacent branches of the pulmonary artery (or *vice versa*) indicating a common capillary network, was demonstrated in infants with transposition with and without interventricular septum defect (III, IV)

The pattern of a pulmobronchial artery substituting for a bronchopulmonary artery as described above, was recognized in a few specimens from infants with isolated transposition (III)

Supplementary systemic-artery supply of the lung

In three of the aorta-injected specimens from infants with *isolated transposition* the systemic-artery supply of the lung was further increased through the presence of

3) The *end-to-side* anastomosis the bronchial artery empties into the much wider pulmonary artery

Normal A few anastomoses between the bronchial and pulmonary arteries were demonstrated in 16 per cent of the late fetal and neonatal subjects. Most of the anastomoses were of the *side-to-side* type, with the inner diameter of the transverse vessel varying from 75 to 100 µ. Only one intrapulmonary anastomosis of *end-to-end* type (diameter 50 µ) and one anastomosis of *end-to-side* type (diameter 35 µ) were found in this part of the series (I)

In the series of subjects from infancy and early childhood, arterial bronchopulmonary anastomoses were demonstrated in 80 per cent. Their number varied considerably from subject to subject, and they were particularly numerous in the two oldest (aged 3 years and 8 months, and 4 years and 7 months) There was, however no evidence of gradual increase with age. The most common type of anastomosis is *side-to-side*. Occasionally two or three bronchial-artery branches join to form the "afferent systemic part of an H-anastomosis. The inner diameter of the transverse vessel of the side-to-side anastomoses ranges up to 300 µ. The next most common type of anastomosis is *end to-end*. The pleural anastomoses of this type were found at the mediastinal aspect of the lung or at the interlobar fissures. The inner diameter of the arterial arch ranges up to 250 µ. The least common type of anastomosis is *end-to-side*. The inner diameter of these anastomoses ranges from 25 to 250 µ (II)

The wall structure of the transverse vessel of a *side-to-side* anastomosis is generally similar to that of the contributing bronchial artery. Towards the pulmonary artery however many of the transverse vessels change their mural elastic pattern into pulmonary artery type with an increase in elastic fibers and the appearance of an external elastic lamina. In the anastomoses of *end-to-end* type there is a gradual change in the mural pattern of the arterial arch from bronchial-artery type to pulmonary-artery type with an intermediate arteriolar portion in the smaller anastomoses. In anastomoses of *end-to-side type* the contributing bronchial artery keeps its usual mural structure up to shortly before the point of anastomosis where the mural elastic pattern changes to pulmonary-artery type (I, II)

From the age of four weeks, fibrin thrombi were observed in the lumen of many anastomoses of all types. Most of these thrombi appeared to have been formed recently but some were in an early stage of organization. From the age of two months and a half many of the bronchial arteries involved in arterial bronchopulmonary anastomoses have intimal layers of smooth muscle cells narrowing the lumen. The bronchial arteries forming H-anastomoses, the transverse branch in particular are most commonly affected. A few anastomoses of *side-to-side* and *end to-end* types are completely obliterated by intimal smooth muscle cells and connective tissue. These closed anastomoses were observed from the age of seven months (II)

Transposition of the great arteries Arterial bronchopulmonary anastomoses of *side-to-side* and *end-to-end* types were demonstrated in 50 per cent of the infants with *isolated transposition* The most common type is *end-to-end* The diameter of the anastomoses ranges from 50 to 125 µ (III)

A few anastomoses of all types were demonstrated in two of the seven infants with

multiple small mediastinal arteries, originating from branches of the thoracic aorta. In the injected specimens, these arteries were visible to the naked eye and appeared to enter the pulmonary parenchyma in the same way as the bronchopulmonary arteries (III)

Comment

The existence of focal bronchial artery supply of alveolar walls in the human neonatal lung has been recognized previously by Küttner (26) Konaschko (25) and Cudkowicz & Armstrong (13) These old observations were recently confirmed by Wagenvoort & Wagenvoort (55 56) who also suggested the term 'bronchopulmonary arteries' as mentioned above.

The bronchial arteries are, embryologically derived from the systemic arteries supplying the *plexus pulmonalis communis*. The systemic artery supply of this plexus is established earlier than its connection with the pulmonary arteries (9 10 32, 36, 41 50 57) This double arterial supply of the capillary plexus of the developing lung is still reflected in the late fetal and neonatal lung through the presence of bronchopulmonary arteries. These arteries normally become obliterated during the first few years of postnatal life (II)

The frequent and extensive occurrence of bronchopulmonary arteries and supplementary systemic arteries in transposition of the great arteries — of isolated type in particular — can be interpreted as a retention of the early fetal vascular pattern or as an intrauterine adaptation to the cardiovascular malformation. It becomes more prominent with postnatal age but does not reach the same extent in the presence of an associated interventricular septum defect (III IV)

In transposition of the great arteries, the bronchopulmonary arteries carry poorly oxygenated blood from the transposed aorta to the respiratory surface of the alveoli. The benefit of this would be increased considerably in the presence of increased systemic venous drainage of the lungs, as pointed out by Ferencz (19) The structure of the pulmonary venous system in transposition of the great arteries, however has not been analyzed hitherto

Arterial bronchopulmonary anastomoses

The term arterial anastomosis is used to imply a precapillary communication between two arterial systems Three forms of arterial bronchopulmonary anastomoses have been recognized

1) The *side to-side* (H) anastomosis the more or less parallell branches of the bronchial and pulmonary arteries are connected by a transverse (or oblique) vessel in the form of a one-step ladder
2) The *end to-end* anastomosis an arterial or arteriolar arch is present between a lobular branch of the pulmonary artery leaving (penetrating) the lobulus and a peribronchial or pleural branch of the bronchial artery Since the contributing bronchial artery often shows branches running peripherally to the arterial arch many of these anastomoses are more or less T shaped the stem of the "T" representing the contributing pulmonary artery

3) The *end-to-side* anastomosis the bronchial artery empties into the much wider pulmonary artery

Normal A few anastomoses between the bronchial and pulmonary arteries were demonstrated in 16 per cent of the late fetal and neonatal subjects. Most of the anastomoses were of the *side-to-side* type, with the inner diameter of the transverse vessel varying from 75 to 100 μ. Only one intrapulmonary anastomosis of *end-to-end* type (diameter 50 μ) and one anastomosis of *end-to-side* type (diameter 35 μ) were found in this part of the series (I)

I the series of subjects from infancy and early childhood, arterial bronchopulmonary anastomoses were demonstrated in 80 per cent. Their number varied considerably from subject to subject, and they were particularly numerous in the two oldest (aged 3 years and 8 months, and 4 years and 7 months) There was, however no evidence of a gradual increase with age The most common type of anastomosis is *side-to-sid* Occasionally two or three bronchial artery branches join to form the afferent systemic part of an H-anastomosis. The inner diameter of the transverse vessel of the side-to-side anastomoses ranges up to 300 μ. The next most common type of anastomosis is *end-to-end* The pleural anastomoses of this type were found at the mediastinal aspect of the lung or at the interlobar fissures. The inner diameter of the arterial arch ranges up to 250 μ. The least common type of anastomosis is *end to-side* The inner diameter of these anastomoses ranges from 25 to 250 μ (II)

The wall structure of the transverse vessel of a *side-to-side* anastomosis is generally similar to that of the contributing bronchial artery Towards the pulmonary artery however many of the transverse vessels change their mural elastic pattern into pulmonary artery type with an increase in elastic fibers and the appearance of an external elastic lamina. In the anastomoses of *end-to-end* type there is a gradual change in the mural pattern of the arterial arch from bronchial artery type to pulmonary artery type with an intermediate arteriolar portion in the smaller anastomoses. In anastomoses of *end-to-side type* the contributing bronchial artery keeps its usual mural structure up to shortly before the point of anastomosis where the mural elastic pattern changes to pulmonary artery type (I II)

From the age of four weeks, fibrin thrombi were observed in the lumen of many anastomoses of all types. Most of these thrombi appeared to have been formed recently but some were in an early stage of organization. From the age of two months and a half many of the bronchial arteries involved in arterial bronchopulmonary anastomoses have intimal layers of smooth muscle cells narrowing the lumen. The bronchial arteries forming H-anastomoses, the transverse branch in particular are most commonly affected. A few anastomoses of *sid-to-side* and *end-to-end* types are completely obliterated by intimal smooth muscle cells and connective tissue. These closed anastomoses were observed from the age of seven months (II)

Transposition of the great arteries Arterial bronchopulmonary anastomoses of *side to-side* and *end-to-end* types were demonstrated in 30 per cent of the infants with *isolated transposition* The most common type is *end-to-end* The diameter of the anastomoses ranges from 50 to 125 μ (III)

A few anastomoses of all types were demonstrated in two of the seven infants with

transposition associated with interventricular septum defect The diameter of these anastomoses ranges from 50 to 350 μ (IV)

In one *end to-end* anastomosis, present in a subject with isolated transposition and Type I pattern, there was some stenosis of the lumen on the pulmonary artery side through cellular intimal cushions Otherwise none of the anastomoses demonstrated in the two series of infants with transposition displayed obliterative features and they did not have the mural structure of "Sperr arteries (III IV)

Comment

The *normal* incidence of arterial bronchopulmonary anastomoses is greater *in infancy and early childhood* than in the *late fetal and neonatal period* indicating that anastomoses are formed during the postnatal development of the lung The reversal of the relative frequencies of arterial bronchopulmonary anastomoses and pulmobronchial arteries after the age of two months suggests that anastomoses — of H type at least — result from the establishment of precapillary communications between pulmobronchial arteries and neighboring ordinary *bronchial* arteries (II)

Another difference between the late fetal neonatal period and infancy-early childhood is the postnatal development of *pleural arterial bronchopulmonary anastomoses*. These structures were not demonstrated in the present study of the late fetal and neonatal lung (I) The existence of pleural anastomoses in the human neonatal lung has been claimed however by other investigators (25 26, 53 59)

The theory suggested by Weibel (57) that arterial bronchopulmonary anastomoses present in the fetal lung disappear later in life was recently supported by Wagenvoort & Wagenvoort (56) who demonstrated fibrous obliteration of anastomoses in one infant, aged one year The present study gives further support to this view It is obvious that anastomoses can be obliterated by intimal muscle bundles, fibrin thrombi and connective tissue (II)

It seems probable that obliteration affects anastomoses without shunt function i.e. superfluous vascular channels The development of "Sperr artery structure in arterial bronchopulmonary anastomoses would then be a process of involution rather than a differentiation towards the specialized function of flow regulation attributed to these vessels (24) The variation in the thickness of the intimal smooth muscle bundles in bronchial artery branches involved in anastomoses of side-to-side type is possibly related to an established direction of flow in the anastomosis, as indicated in Table 2.

Table 2

afferent BA	PA → BA
efferent BA	PA ← BA
transverse vessel	none
neither	not established

PA = pulmonary artery
BA = bronchial artery

In *transposition of the great arteries* with or without an interventricular septum defect (III IV) the arterial bronchopulmonary anastomoses are essentially normal in type. The over representation of anastomoses of

end-to-end type in specimens from infants with isolated transposition is probably related to the extensive occurrence of bronchopulmonary arteries in these subjects. In regions of the pulmonary parenchyma supplied by bronchopulmonary arteries, there are — as a rule — capillary communications between these arteries and adjacent branches of the pulmonary artery. There is a gradual transition between this pattern and the pattern of small arterial bronchopulmonary anastomoses of end-to-end type (III).

The sources of error (overlapping etc., see p. 70) involved in the demonstration and measuring of pulmobronchial arteries naturally have the same influence on the study of arterial bronchopulmonary anastomoses. As for the pulmobronchial arteries, there is a degree of uncertainty in the classification, counting and measurement of the anastomoses. The figures given above on the incidence and size of anastomoses should therefore be regarded as approximate. The findings of the present study concerning the size of the arterial bronchopulmonary anastomoses in the normal human perinatal lung agree, however, fairly well with recent histologic observations by Wagenvoort & Wagenvoort (55, 56).

The functional significance of the arterial bronchopulmonary anastomoses is probably low both in the normal infant lung and in transposition of the great arteries. Their normal functional capacity is, however, probably somewhat greater in infancy and early childhood than in the late fetal and neonatal period (I, II). In transposition of the great arteries — of isolated type in particular — a more important pathway for the systemic blood to the alveolar capillary bed is offered by the bronchopulmonary arteries (III, IV).

transposition associated with interventricular septum defect The diameter of these anastomoses ranges from 50 to 350 μ (IV)

In one *end to-end* anastomosis present in a subject with isolated transposition and Type I pattern, there was some stenosis of the lumen on the pulmonary-artery side through cellular intimal cushions Otherwise none of the anastomoses demonstrated in the two series of infants with transposition displayed obliterative features and they did not have the mural structure of "Sperr" arteries (III IV)

Comment

The *normal* incidence of arterial bronchopulmonary anastomoses is greater in *infancy and early childhood* than in the *late fetal and neonatal period* indicating that anastomoses are formed during the postnatal development of the lung The reversal of the relative frequencies of arterial bronchopulmonary anastomoses and pulmobronchial arteries after the age of two months suggests that anastomoses — of H-type at least — result from the establishment of precapillary communications between pulmobronchial arteries and neighboring ordinary bronchial arteries (II)

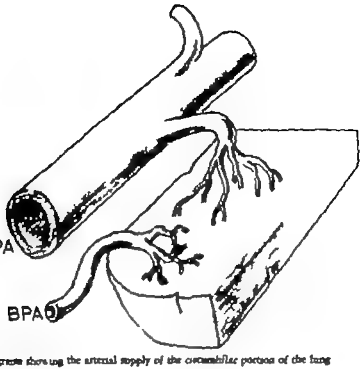

Fig 2 Diagrams showing the arterial supply of the circumlobular portion of the lung

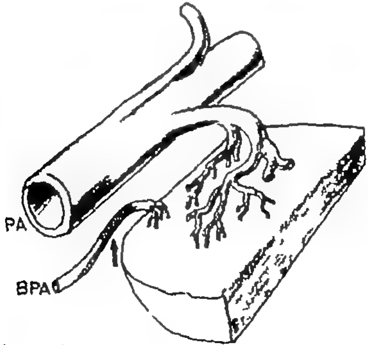
A Normal late fetal and neonatal period The circumlobular portion of the lung is supplied by abrupt branches of the pulmonary artery (PA) and by bronchopulmonary arteries (BPA)



B Normal infancy and childhood Involution with obliteration of bronchopulmonary arteries (BPA, arrow)

CONCLUSION

Normal intrapulmonary arterial pattern The pulmonary arterial system generally branches with the bronchi, with the exception of "abrupt" branches present particularly in the "medullary" zone of the lung

Pulmobronchial arteries occur inconsistently and contribute to the arterial supply of a few bronchi

The ordinary bronchial arteries generally follow the course of the bronchi The diameter of the main bronchial arteries in the hilus of the lung increases with fetal age but is fairly constant during infancy and early childhood From the age of 10 weeks, some of the bronchial arteries have the structure of "Sperr" arteries with intimal bundles of smooth muscle cells Focal bronchial artery supply of small areas of the pulmonary parenchyma proper *via* bronchopulmonary arteries is a regular feature of the late fetal and neonatal lung (Fig 2 A) The bronchopulmonary arteries become narrowed and obliterated in early infancy and can rarely be demonstrated microangiographically after the immediate neonatal period (Fig 2 B)

Arterial bronchopulmonary anastomoses (of side to-side, end to-end and end-to-side types) occur inconsistently They are more numerous in infancy and early childhood than in the late fetal neonatal period The "Sperr"-artery structure of bronchial arteries particularly affects branches involved in arterial bronchopulmonary anastomoses and from the age of seven months some anastomoses are completely obliterated.

The intrapulmonary arterial pattern in transposition of the great arteries Abnormal patterns of the pulmonary arterial system are consistently present, either in the form of funnel shaped narrowing of intralobular arteries (Type I) or in the form of increased tortuosity of intralobular arteries (Type II) Furthermore, in some cases the abrupt branches are abnormal in type with octopus like ramifications.

Pulmobronchial arteries are generally about as frequent as in the normal infant. In many instances, however they diverge from the normal pattern by deviating from the bronchial wall in their terminal course to end as alveolar capillaries

The bronchial arteries are wider than in the normal neonatal lung and supply a large portion of the pulmonary parenchyma proper in the "medullary" zone of the lung *via* bronchopulmonary arteries (Fig 2 C) Obliteration of branches of the pulmonary artery was occasionally observed in areas supplied by bronchopulmonary arteries indicating that the arterial supply of these areas has been taken over by the bronchial arterial system (Fig 2 D)

In some cases the systemic artery supply of the pulmonary parenchyma proper is further increased by small mediastinal arteries running to the neighboring dorsal portion of the lungs

Arterial bronchopulmonary anastomoses occur inconsistently They are few in number and they are usually end to-end

The intrapulmonary arterial pattern in transposition of the great arteries associated with interventricular septum defect The pulmonary arterial pattern is either normal

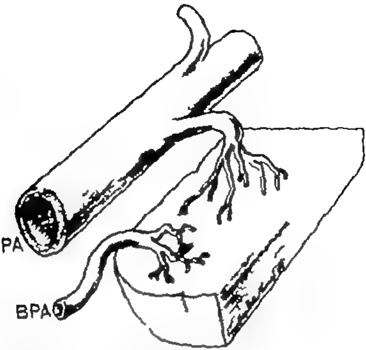


Fig. 2. Diagrams showing the arterial supply of the circumhilar portion of the lung.

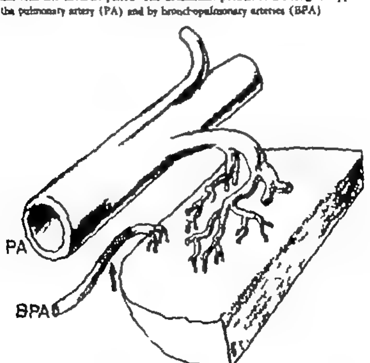
A. Normal late fetal and neonatal period. The circumhilar portion of the lung is supplied by abrupt branches of the pulmonary artery (PA) and by bronchopulmonary arteries (BPA).



B. Normal infancy and childhood. Involution with obliteration of bronchopulmonary arteries (BPA, arrow).

CONCLUSION

Normal intrapulmonary arterial pattern The pulmonary arterial system generally branches with the bronchi, with the exception of "abrupt" branches present particularly in the "medullary" zone of the lung

Pulmobronchial arteries occur inconsistently and contribute to the arterial supply of a few bronchi

The ordinary bronchial arteries generally follow the course of the bronchi. The diameter of the main bronchial arteries in the hilus of the lung increases with fetal age but is fairly constant during infancy and early childhood. From the age of 10 weeks, some of the bronchial arteries have the structure of "Sperr" arteries with intimal bundles of smooth muscle cells. Focal bronchial-artery supply of small areas of the pulmonary parenchyma proper *via* bronchopulmonary arteries, is a regular feature of the late fetal and neonatal lung (Fig 2 A). The bronchopulmonary arteries become narrowed and obliterated in early infancy and can rarely be demonstrated microangiographically after the immediate neonatal period (Fig 2 B)

Arterial bronchopulmonary anastomoses (of side-to-side, end to-end and end to-side types) occur inconsistently. They are more numerous in infancy and early childhood than in the late fetal neonatal period. The 'Sperr' artery structure of bronchial arteries particularly affects branches involved in arterial bronchopulmonary anastomoses and from the age of seven months some anastomoses are completely obliterated

The intrapulmonary arterial pattern in transposition of the great arteries Abnormal patterns of the pulmonary arterial system are consistently present, either in the form of funnel shaped narrowing of intralobular arteries (Type I) or in the form of increased tortuosity of intralobular arteries (Type II). Furthermore, in some cases the abrupt branches are abnormal in type with octopus like ramifications.

Pulmobronchial arteries are generally about as frequent as in the normal infant. In many instances, however they diverge from the normal pattern by deviating from the bronchial wall in their terminal course to end as alveolar capillaries

The bronchial arteries are wider than in the normal neonatal lung and supply a large portion of the pulmonary parenchyma proper in the "medullary" zone of the lung, *via* bronchopulmonary arteries (Fig 2 C). Obliteration of branches of the pulmonary artery was occasionally observed in areas supplied by bronchopulmonary arteries indicating that the arterial supply of these areas has been taken over by the bronchial arterial system (Fig 2 D)

In some cases, the systemic-artery supply of the pulmonary parenchyma proper is further increased by small mediastinal arteries running to the neighboring dorsal portion of the lungs.

Arterial bronchopulmonary anastomoses occur inconsistently. They are few in number and they are usually end to-end

The intrapulmonary arterial pattern in transposition of the great arteries associated with interventricular septum defect The pulmonary arterial pattern is either normal

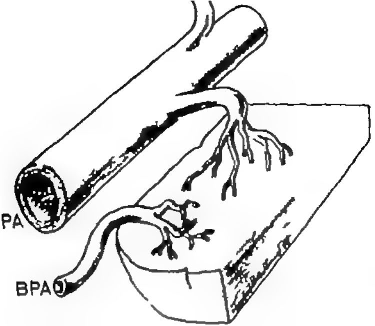


Fig 2 Diagrams showing the arterial supply of the circumhilar portion of the lung

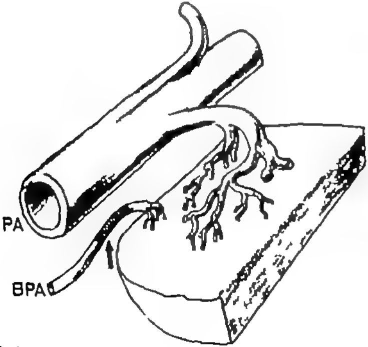
A Normal late fetal and neonatal period The circumhilar portion of the lung is supplied by abrupt branches of the pulmonary artery (PA) and by bronchopulmonary arteries (BPA)



B Normal infancy and childhood Involution with obliteration of bronchopulmonary arteries (BPA, arrow)

CONCLUSION

Normal intrapulmonary arterial pattern The pulmonary arterial system generally branches with the bronchi, with the exception of "abrupt" branches present particularly in the "medullary" zone of the lung

Pulmobronchial arteries occur inconsistently and contribute to the arterial supply of a few bronchi

The *ordinary bronchial* arteries generally follow the course of the bronchi. The diameter of the main bronchial arteries in the hilus of the lung increases with fetal age but is fairly constant during infancy and early childhood. From the age of 10 weeks, some of the bronchial arteries have the structure of "Sperr" arteries with intimal bundles of smooth muscle cells. Focal bronchial artery supply of small areas of the pulmonary parenchyma proper *via* bronchopulmonary arteries is a regular feature of the late fetal and neonatal lung (Fig 2 A) The bronchopulmonary arteries become narrowed and obliterated in early infancy and can rarely be demonstrated microangiographically after the immediate neonatal period (Fig 2 B)

Arterial bronchopulmonary anastomoses (of side-to-side, end to-end and end-to-side types) occur inconsistently They are more numerous *in infancy and early childhood* than in the late fetal neonatal period. The "Sperr" artery structure of bronchial arteries particularly affects branches involved in arterial bronchopulmonary anastomoses, and from the age of seven months some anastomoses are completely obliterated.

The intrapulmonary arterial pattern in transposition of the great arteries Abnormal patterns of the pulmonary arterial system are consistently present, either in the form of funnel shaped narrowing of intralobular arteries (Type I) or in the form of increased tortuosity of intralobular arteries (Type II) *Furthermore, in some cases the* abrupt branches are abnormal in type with octopus like ramifications

Pulmobronchial arteries are generally about as frequent as in the normal infant. In many instances, however they diverge from the normal pattern by deviating from the bronchial wall in their terminal course to end as alveolar capillaries.

The bronchial arteries are wider than in the normal neonatal lung and supply a large portion of the pulmonary parenchyma proper in the "medullary" zone of the lung, *via* bronchopulmonary arteries (Fig 2 C) Obliteration of branches of the pulmonary artery was occasionally observed in areas supplied by bronchopulmonary arteries indicating that the arterial supply of these areas has been taken over by the bronchial arterial system (Fig 2 D)

In some cases, the systemic artery supply of the pulmonary parenchyma proper is further increased by small mediastinal *arteries running* to the *neighboring* dorsal portion of the lungs.

Arterial bronchopulmonary anastomoses occur *inconsistently They* are few in number and they are usually end to-end

The intrapulmonary arterial pattern in transposition of the great arteries associated with interventricular septum defect The pulmonary arterial pattern is either normal

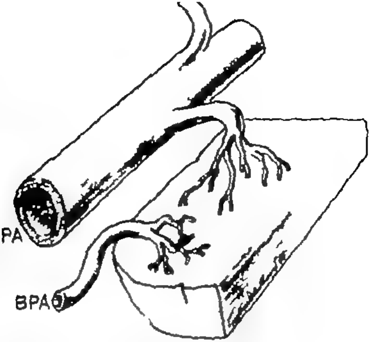


Fig. 2 Diagrams showing the arterial supply of the circumlobular portion of the lung

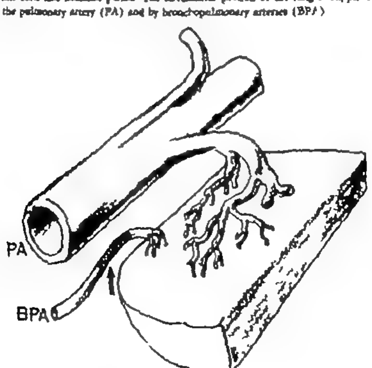
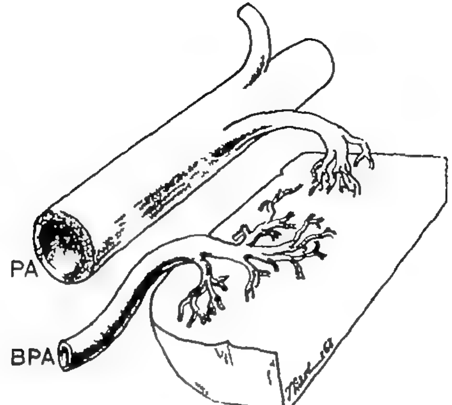
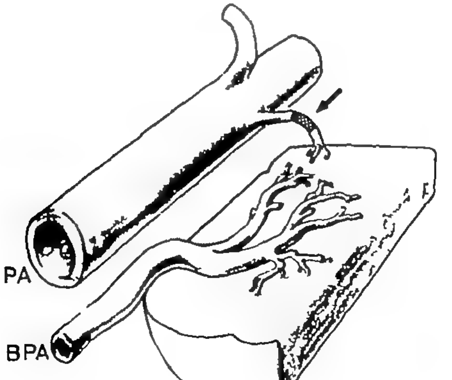
A. Normal late fetal and neonatal period. The circumlobular portion of the lung is supplied by abrupt branches of the pulmonary artery (PA) and by bronchopulmonary arteries (BPA)



B. Normal infancy and childhood. Involution with obliteration of bronchopulmonary arteries (BPA, arrow)



C. Isolated transposition of the great arteries, immediate neonatal period. Wide bronchopulmonary arteries (BPA) enter the circumhilar portion of the lung.



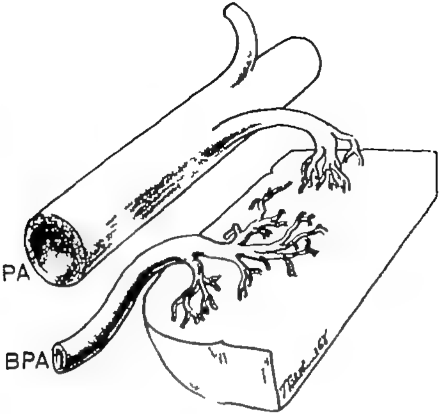
D. Isolated transposition of the great arteries, infancy. The bronchopulmonary arteries (BPA) are further increased in size and some abrupt branches of the pulmonary artery (PA) are obliterated (arrow).

in type or the intralobular arteries are tortuous.

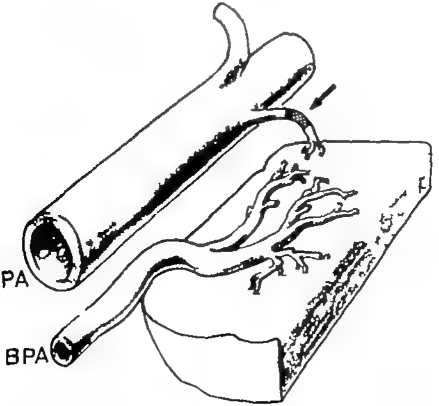
Pulmobronchial arteries are few in number and occur inconsistently. They are generally normal in type and of normal size.

The bronchial artery supply of the pulmonary parenchyma proper via bronchopulmonary arteries, is within normal limits or moderately increased.

Arterial bronchopulmonary anastomoses are inconsistent and few in number. Their structure and size are essentially normal.



C. Isolated transposition of the great arteries, immediate neonatal period. Wide bronchopulmonary arteries (BPA) enter the circumhilar portion of the lung



D. Isolated transposition of the great arteries, infancy. The bronchopulmonary arteries (BPA) ar further increased in size and some abrupt branches of the pulmonary artery (PA) are obliterated (*arrow*)

ACKNOWLEDGEMENTS

My thanks are first due to Dr. Björn Ivemark, my teacher in pediatric pathology who initiated this work and made available to me the resources of the Department of Pediatric Pathology, Karolinska Sjukhuset. I wish to thank him for constant support and encouragement during the study.

Most valuable advice and criticism were also given by Prof. Bo Thorell and by Drs. Arne Ljungqvist, Crawford Grant and Sigurd Söderlund.

This work was further facilitated by the generous support of Dr. Åke G. H. Lindgren, to whom I express my gratitude.

I am grateful to Ingemar Söderlund, medical artist, for making the diagrams of the study.

For skillful technical assistance throughout the work, I am indebted to Inger Nyström and Birgitta Andréasson.

These studies were supported by grants from the Swedish National Association against Heart and Chest Diseases, Karolinska Institutets "Reservationsanslag", "Expressens Prenatalforskningsfond", "Carin Tryggers fond" and "Stiftelsen Therese och Johan Anderssons Minne".

SUMMARY

Microangiographic and histologic studies of the pulmonary and bronchial arterial systems were carried out on 52 normal human fetuses, infants and children and on a series of 17 infants with transposition of the great arteries isolated or associated with an interventricular septum defect. *Particular attention was paid to various types* of aberrations from the basic arterial pattern arterial bronchopulmonary anastomoses, pulmobronchial arteries and bronchopulmonary arteries.

The arterial bronchopulmonary anastomoses are of essentially the same type in normal cases as in transposition of the great arteries. The normal number of anastomoses is greater in infancy and early childhood than in the late fetal and neonatal period. From the age of a few months, however many of the anastomoses become narrowed or obliterated. Abnormal pattern of the pulmonary arterial system, including abnormal pulmobronchial arteries, is a prominent feature in isolated transposition, less *so in transposition associated with inter*ventricular septum defect. In isolated transposition there is a considerable increase in the bronchial artery supply of the pulmonary parenchyma proper *via* bronchopulmonary arteries. In transposition associated with interventricular septum defect, the bronchial artery supply of the pulmonary parenchyma has a normal extent or is only moderately increased.

INTRODUCTION

The transport and metabolism of lipids by the human placenta is of unknown clinical significance. If we presume that the fetus, like the adult, cannot synthesize the essential fatty acids of the linoleate family then these fatty acids must be derived from the maternal circulation and most likely cross the placenta. The normal growth of newborn infants is dependent upon an adequate supply of the essential fatty acids (1) and fetal growth must be similarly dependent. This is the basis of our interest in placental lipid transport and metabolism.

Previously the placenta has been considered impermeable to most lipids. This has been substantiated by the general lack of correlation between maternal and umbilical cord blood lipid levels (2, 3 4 5 6, 7 8 9). The variables which may obscure such correlation are, of course, the placental and fetal uptake, synthesis, and interconversion of lipids.

The dissimilarity of the fatty acid composition of maternal and umbilical cord blood lipids (2, 4 10, 11 1., 13 14 15) is similarly used as an argument against transport and has the same weakness. Another error in logic in the use of fatty acid compositional studies is that they are frequently calculated as percentages so that no absolute quantity of an individual fatty acid is expressed

Early perfusion and feeding studies in animal showed no or little transport across the placenta of phospholipids (16, 17), cholesterol (18), and fatty acids (19). Recent animal studies, using more physiologic techniques, are showing very significant levels of transport. As always there is the basic problem of extrapolating data from animal experiments to humans.

It is our impression that the maternal circulation is the probable source of a good portion of the placental and fetal lipids and that placental metabolism notably alters maternal lipids before they enter the fetal circulation. The purpose of this review is to discuss those data that support or refute this view

CHANGES IN LIPIDS WITH PREGNANCY AND DELIVERY

During human pregnancy the concentration of every general lipid fraction increases (21 22, 23 .4 25 26, 27 28, 29 30 31 32, 33 34). The only exception to this is the phospholipid, lysolecithin, which decreases (35) The maternal values at delivery are given in Table 1 No cause for the hyperlipidemia of pregnancy is agreed upon. It is interesting to consider the possibility that the placenta and fetus contribute lipids to the maternal circulation causing the hyperlipidemia. Although the hyperlipidemia in the mother decreases in the first post partum days (24 36 37 38) and, in the case of free fatty acids, within sixty minutes (39), normal levels are not reached until two to five days for the free fatty acids (24 37) and two to six months for the other lipid fractions (31 32, 40) This slow decline argues against the simple mechanism of a fetoplacental contribution to the maternal circulation.

One very interesting and unexplained point has arisen from the fatty acid compositional studies. In comparing maternal and fetal fatty acids from cholesterol esters (2, 14) lecithin (2, 4, 15) and cephalin (2, 15) the relative per cent of linoleic acid in the fetus is lower and that of arachidonate higher (see Tables 5 through 7). Does this mean that the maternal arachidonate esters are preferentially crossing the placenta? If so we might expect to see a difference in pregnant and nonpregnant fatty acid patterns in the cholesterol ester lecithin, and cephalin fractions. Very few such studies are either reported and none give enough data for answering this question.

INFANT LIPID CHANGES FOLLOWING DELIVERY

The umbilical cord blood levels of the lipid fractions are presented in Table 1 and are consistently lower than the maternal values (2, 3 4 5 7 13 14 42, 43 44 45 46, 47 48) with the exception of lysolecithin (4 35). Following delivery in-

than at term. This finding is not supported by all the available data (61) and needs to be repeated with larger number of samples.

The presence of linoleic acid and its decline after birth strongly suggest a maternal source. There are no published reports of free fatty acids crossing the placenta in humans. In laboratory animals such as the rabbit C¹ free fatty acids administered to the mother lead to C in the fetal free fatty acids (62). The same is true for the sheep (63). In monkeys free fatty acids are rapidly transferred from mother to fetus. An interesting and contradictory point of this work is that at term the uptake by the placenta and transfer to the fetus of linoleic acid is greater than earlier in gestation (64).

We can only infer that, in humans, as in other animals, free fatty acids may enter the placenta from the maternal circulation and be extruded into the fetal circulation as free fatty acids. But this transfer is apparently not entirely direct or quantitative. It does not, for example, easily explain the high percentage of arachidonic acid found in the free fatty acid fraction of the placenta (see Table). The free fatty acid composition of the placenta is sufficiently different from that of the mother to suggest that some of the components of this free fatty acid pool are derived from other sources than the maternal circulation (57). If transplacental transport of essential fatty acids is primarily as free fatty acids, a very selective mechanism must be at work favoring arachidonic acid. It seems probable that the placenta may alter the pattern of free fatty acids presented to it before they enter the fetal circulation.

The placenta has several interesting possibilities in the realm of free fatty acid metabolism. There is no information to show if placental tissue carries out beta oxidation of fatty acids. The synthesis of long chain fatty acids from C¹ acetate by a purified placental extract is reported. This synthesis is enhanced by estradiol through stimulation of a pyridine nucleotide transhydrogenase. The fatty acid formed is identified as palmitate but no data is given to show if further chain elongation or desaturation occurs (65). If the placenta is capable of converting linoleic acid to arachidonic acid, it could explain the accentuation of arachidonic acid in the placental and fetal lipids.

There is a non-dialyzable material in antepartum maternal serum which liberates free fatty acids from rat adipose tissue. This activity is not

Tables 1 Fatty acid components are expressed in the following manner: the first number represents the number of carbon atoms, following the colon is the number of unsaturated bonds, following the ω the carbon number of the first unsaturated bond counting from the methyl end of the fatty acid. Components preceded by an asterisk are unidentified and expressed by their equivalent chain length. Fatty acids labeled 18:1ω9 and 18:3ω6 may have ω7 fatty acids included in the percentage since these are probably not separated under the reported conditions. The letter N means not reported.

Table 1 *Lipid components at birth*

Values for components 1 through 5 are from the work of Nelson *et al* (3). Total phospholipid value is derived by multiplying the lipid phosphorus in mg per cent by 25 Individual phospholipid values (components 6–11) in maternal and umbilical cord blood are from the data of Zee (4). Individual phospholipid values (components 6–11) in placental tissue are from the data of Nelson *et al* (134). Lipoprotein values (components 12 and 13) are from the data of Brown *et al.* (7).

Component	Mother's blood	Placental tissue	Umbilical cord blood
Microequivalent per L or per K of tissue (wet weight)			
1 Free fatty acids	1250+78	4922+664	586+78

13 Beta lipoproteins	847+176	N	224+61

fant plasma free fatty acid values rise to a maximum between thirty minutes (49) and twelve hours (50) The triglycerides have risen significantly at twelve hours (13) perhaps representing the hepatic incorporation of mobilized free fatty acids into triglycerides. The total cholesterol values do not change in the first twelve hours (13) Certainly there is apparently no acute decline in any lipid fraction upon delivery indicating that either there is at birth no dependence upon maternal or placental lipids or that the infant quickly asserts his control over circulating lipid levels.

Carbohydrate fed newborn infants show no increase in lipoproteins or lipids as long as proteins and amino acids are excluded from their diet (51) This suggests that the elevation in lipids following birth (and perhaps the levels before birth) is a function of the protein level rather than a reflection of placental impermeability to certain lipid classes.

FREE FATTY ACIDS

Transport and metabolism. It is difficult to draw conclusions about the placental transport of free fatty acids at delivery because of the complexity of the free fatty acid changes in the perinatal period in both the mother's and infant's circulation. Maternal circulating free fatty acids rise even more during labour (25 37 52, 53) probably due to endogenous catecholamine release. In the normal infant the rise in the circulating free fatty acid level correlates with a falling glucose level (46 54) and is due to lipolysis as evidenced by an elevation of circulating glycerol (50) These free fatty acids are being oxidized to ketone bodies (55)

When maternal free fatty acid levels are further elevated by epinephrine infusion no change in umbilical cord blood free fatty acids occurs (56) This would argue against transport. However the variables are numerous in such experiments. For example it has been shown that elevating the maternal glucose level leads to an elevated umbilical cord blood glucose level and a lowered umbilical cord blood free fatty acid level This effect occurs with a 5 per cent dextrose solution and no further lowering of the umbilical cord blood free fatty acid level occurs when a 20 per cent dextrose solution is used although the maternal free fatty acid level declines further (40) It may be that phenomena such as this obscure a direct correlation between maternal and fetal free fatty acid levels.

Several studies show that the umbilical cord blood free fatty acid pattern at birth does not resemble the mother's circulating free fatty acid patterns (2, 10, 57) or the newborn's adipose tissue fatty acid pattern (see Tables 2 and 3) (58 59 60) At two to four hours of age the infant's plasma free fatty acids resemble more closely the newborn adipose tissue (10 60) Especially pertinent is the fall in the relative per cent of linoleic acid which we presume to be of maternal origin The reasonable assumption is that, *in utero* the fetal free fatty acids are derived both from fetal sources and selective placental transport from the mother

The triglyceride fatty acid pattern of premature infant adipose tissue more closely resembles that of the mother (58 59) This suggests that earlier in gestation the maternal free fatty acids may contribute more directly to the fetal adipose tissue

When maternal free fatty acid levels are further elevated by epinephrine infusion no change in umbilical cord blood free fatty acids occurs (56). This would argue against transport. However the variables are numerous in such experiments. For example it has been shown that elevating the maternal glucose level leads to an elevated umbilical cord blood glucose level and a lowered umbilical cord blood free fatty acid level. This effect occurs with a 5 per cent dextrose solution and no further lowering of the umbilical cord blood free fatty acid level occurs when a 20 per cent dextrose solution is used although the maternal free fatty acid level declines further (40). It may be that phenomena such as this obscure a direct correlation between maternal and fetal free fatty acid levels.

Several studies show that the umbilical cord blood free fatty acid pattern at birth does not resemble the mother's circulating free fatty acid patterns (2, 10, 57) or the newborn's adipose tissue fatty acid pattern (see Tables 2 and 3) (58, 59, 60). At two to four hours of age the infant plasma free fatty acids resemble more closely the newborn adipose tissue (10, 60). Especially pertinent is the fall in the relative per cent of linoleic acid which we presume to be of maternal origin. The reasonable assumption is that, *in utero* the fetal free fatty acids are derived both from fetal sources and selective placental transport from the mother.

The triglyceride fatty acid pattern of premature infant adipose tissue more closely resembles that of the mother (58, 59). This suggests that earlier in gestation the maternal free fatty acids may contribute more directly to the fetal adipose tissue

Table 4 *Fatty acid composition of triglycerides*

Maternal and umbilical cord fatty acids are from the data of Renkonen (2) while placental tissue data are from Sprecher and Robertson (81). *Figures represent the mean area per cent followed by one standard deviation. The figures in parentheses represent the number of samples.*

fatty acids of the maternal triglycerides do not appear in the fetal triglycerides (71). The fatty acid pattern of triglycerides in human tissue is presented in Table 4.

It is hard to know the significance of much enzymatic data. For example it is reported that the clearing factor of post-heparin maternal plasma is progressively depressed during the second and third trimesters and begins returning to normal one to four days after delivery (72). Does this indicate that there is less lipoprotein lipase at the placental surface during late pregnancy and therefore less formation of diglycerides and monoglycerides to enter the placenta? Lipoprotein lipase activity is present in placental tissue (73) and in newborn plasma before feeding (74).

Lipase activity is present in placental tissue as measured by the hydrolysis of triacetin (75). Amnion cell homogenates hydrolyze triolein (76). The histochemical search for lipases in placental tissue varies from negative results (77) to the finding of lipase activity in very early syncytial cells and its persistence until term with a sharp decline at parturition (78). Serum lipase activity is present in umbilical cord blood indicating its presence in fetal tissues at birth (79). Placental lipase activity should be studied using those triglycerides present in maternal and placental tissue.

Placental tissue will incorporate C^{14} acetate into triglycerides. Because of differences in the rate at which free fatty acids, monoglycerides, diglycerides, and triglycerides are labeled, it is suggested that there is a slow synthetic pathway in which palmitic and stearic acid are synthesized *de novo* and then esterified to form monoglyceride, diglyceride, and triglyceride, and a rapid pathway where a labeled polyenoic acid is esterified to diglyceride to form triglyceride. It is also suggested, without proof, that this polyenoic acid is arachidonic acid formed from the chain desaturation and elongation of linoleate (80). This reaction has not yet been demonstrated directly in placental tissue. The proposed mechanism of rapid triglyceride synthesis utilizing arachidonic acid would explain the high relative percent of arachidonic acid (see Table 4) in placental tissue triglycerides (81).

Summary (see Fig. 2). It seems probable that triglycerides do not pass intact across the placenta. However maternal triglycerides at the placental border may be acted upon by lipoprotein lipase to produce fatty acids and other glycerides which may enter the placental cells. Placental tissue synthesizes triglycerides and these are probably subject to lipase activity and contribute their fatty acids to the placental fatty acid pool which may then be passed into the fetal circulation. The triglycerides of the fetal circulation probably arise from the liver synthesis of triglycerides although triglycerides synthesized in the placenta may be

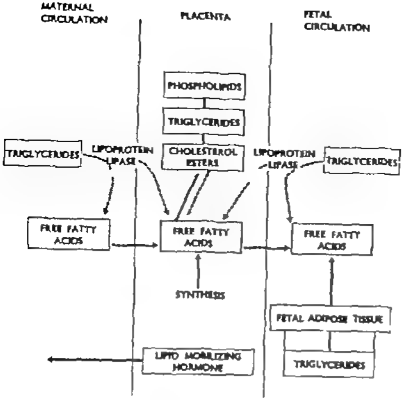

Fig. 1

present in postpartum serum. It is found in placental homogenates and in the serum of a non-pregnant patient with choriocarcinoma (66) Therefore it originates in the placenta. It is probably similar to the previously described growth hormone-prolactin produced by the placenta and known to have free fatty acid mobilizing capabilities (67) It is suggested that this lipid mobilizing action leads to glucose conservation in the mother and thereby assures maximum transfer of glucose to the fetus The levels of this hormone in the fetal circulation are quite low and probably exert no effect on fetal lipid metabolism (68) It would be interesting to know if the free fatty acids mobilized by this substance are the same as those mobilized by hypoglycemia in a non-pregnant subject.

Summary (see Fig 1) It appears likely that specific free fatty acids in the maternal circulation may enter the placental tissue and pass into the fetal circulation. The free fatty acid pattern of the infant's circulation after birth (and perhaps before birth) may be altered by the mobilization of free fatty acids from fetal adipose tissue. Whether the free fatty acid pattern in the fetal circulation is altered by the presence of fatty acids synthesized or altered by the placenta or in other areas of the fetus is not known The free fatty acid pool of the placenta may be added to by the hydrolysis of maternal triglycerides at the placental membrane by lipoprotein lipase. Hydrolysis of glycerides, cholesterol esters, and phospholipids within the placenta may also add to the placental and fetal free fatty acid pool The placenta, itself releases a lipid mobilizing hormone which causes an increased mobilization of free fatty acids in the mother

TRIGLYCERIDES

Transport and metabolism. There are no reported studies dealing directly with the passage of intact triglycerides across the placenta. Many animal studies using diets of different oils whose triglycerides contain various fatty acid patterns have been reported. The only available work in humans involves mothers given cod liver oil or sesame oil prior to surgical abortions. This meagre data suggests that the triglyceride fatty acids may cross the placenta (69) In animals such as the guinea pig the data is clearer but not revealing as to the form or mechanism of passage (70) Data from the fatty acid patterns of lipids in fetal and maternal sheep shows that the exogenous trans-

fatty acids of the maternal triglycerides do not appear in the fetal triglycerides (71) The fatty acid pattern of triglycerides in human tissue is presented in Table 4

It is hard to know the significance of much enzymatic data. For example, it is reported that the clearing factor of post-heparin maternal plasma is progressively depressed during the second and third trimesters and begins returning to normal one to four days after delivery (72). Does this indicate *that there is less lipoprotein lipase* at the placental surface during late pregnancy and therefore less formation of diglycerides and monoglycerides to enter the placenta? Lipoprotein lipase activity is present in placental tissue (73) and in newborn plasma before feeding (74).

Lipase activity is present in placental tissue as measured by the hydrolysis of triacetin (75). Amnion cell homogenates hydrolyze triolein (76) The histochemical search for lipases in placental tissue varies from negative results (77) to the finding of lipase activity in very early syncytial cells and its persistence until term with a sharp decline at parturition (78). Serum lipase activity is present in umbilical cord blood indicating its presence in fetal tissues at birth (79). Placental lipase activity should be studied using those triglycerides present in maternal and placental tissue

Placental tissue will incorporate C[14] acetate into triglycerides. Because of differences in the rate at which free fatty acids, monoglycerides, diglycerides, and triglycerides are labeled, it is suggested that there is a slow synthetic pathway in which palmitic and stearic acid are synthesized *de novo* and then esterified to form monoglyceride, diglyceride and triglyceride, and a rapid pathway where labeled polyenoic acid is esterified to diglyceride to form triglyceride. It is also suggested, without proof, that this polyenoic acid is arachidonic acid formed from the chain desaturation and elongation of linoleate (80). This reaction has not yet been demonstrated directly in placental tissue. The proposed mechanism of rapid triglyceride synthesis utilizing arachidonic acid would explain the high relative percent of arachidonic acid (see Table 4) in placental tissue triglycerides (81).

Summary (see Fig. 2). It seems probable that triglycerides do not pass intact across the placenta. However maternal triglycerides at the placental border may be acted upon by lipoprotein lipase to produce fatty acids and other glycerides which may enter the placental cells. Placental tissue synthesizes triglycerides and these are probably subject to lipase activity and contribute their fatty acids to the placental fatty acid pool which may then be passed into the fetal circulation. The triglycerides of the fetal circulation probably arise from the liver synthesis of triglycerides although triglycerides synthesized in the placenta may be another source.

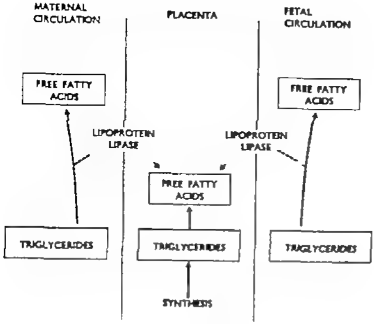

Fig. 2

CHOLESTEROL AND CHOLESTEROL ESTER

Transport and metabolism In the pregnant *rat* fed deuterated cholesterol the cholesterol reaches fetal tissues (82) In the *rat* about 80 percent of the placental cholesterol is derived from the maternal circulation and about 20 percent from cholesterol synthesized in the fetus or placenta. In the *rat* fetus the percent of cholesterol derived from the maternal circulation decreases from about 50 to 70 per cent at twelve to thirteen days of gestation to 15 to 20 per cent at the twentieth day of gestation (83) Similar results are reported with *rabbits* and *guinea pigs* In the *guinea pig* when the mother is fed a cholesterol free diet 20 to 24 per cent of the fetal serum cholesterol is derived from the mother When the mother s diet contained cholesterol 52 to 65 per cent of the fetal serum cholesterol was derived from the mother In both cases the newborn *guinea pig s* circulating level of cholesterol was the same (84) This is a striking example of the fetal control of circulating lipid levels in the presence of varying degrees of placental transport. It also demonstrates the error in presuming no placental transport when maternal and fetal circulating lipid levels show no correlation.

In these studies no data are presented regarding the transfer of cholesterol esters. In the human maternal circulation one source of cholesterol esters is the enzymatic transfer of a fatty acid from lecithin to cholesterol (85) If cholesterol esters do not cross the placenta, the rate of this *transesterification reaction may* determine how much free cholesterol is available for transfer The transesterification reaction occurs also in the newborn infant s blood (86) This is one possible explanation of the higher relative per cent of arachidonic acid in umbilical cord cholesterol esters. When absolute levels of individual cholesterol esters are measured it is found that the ratio of fetal to maternal cholesteryl arachidonate is greater in term than in premature infants (1) The cause of this variation with gestational age is unknown

In placental tissue cholesterol is synthesized *de novo* from acetate and mevalonate. However the synthesis of cholesterol is minimal compared to other sterols (87) Placental tissue will also form cholesterol esters from fatty acids and endogenous cholesterol (76 88) Since the free fatty acid pool of the placenta contains a high relative per cent of arachidonic acid (see Table 2) cholesterol esters formed in the placenta should contain relatively large amounts of arachidonic acid. As can be seen in Table 5 placental tissue falls between maternal and fetal blood in its relative per cent of arachidonic acid These data do not allow any conclusions about the origin of *fetal cholesterol* esters Apparently cholesterol esters are not hydrolyzed by the placenta (76)

Table 5 *Fatty acid composition of cholesterol esters*

Maternal and umbilical cord fatty acids are from the data of Renkonen (2) hile placental fatty acids are from Sprecher *et al.* (24). Figures represent the mean area per cent followed by one standard deviation. The figures in parenthese represent the number of samples.

Summary (see Fig. 3). It seems probable that cholesterol crosses from the maternal to the fetal circulation No information about cholesterol esters is available. In placental tissue cholesterol can be synthesized *de novo* and then esterified with fatty acid. It is unknown if the cholesterol esters formed in the placenta will enter the fetal circulation. Cholesterol esters are apparently not hydrolyzed in placental tissue. In the maternal and fetal serum cholesterol esters are formed by the transfer of a fatty acid from lecithin to cholesterol.

PHOSPHOLIPIDS

Transport and metabolism. In the pregnant *rat* injected with labelled phospholipids small amounts of radioactivity are found in the fetal phospholipids (16). In *rabbits* similarly treated the

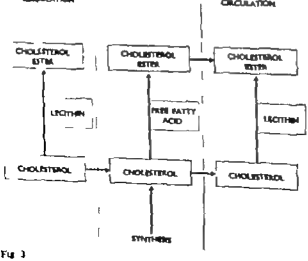

Fig 3

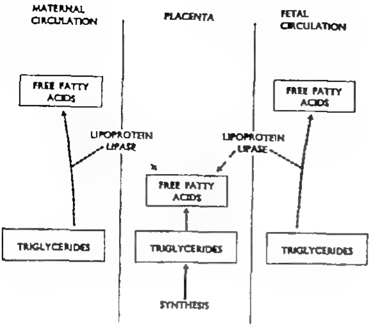

Fig. 2

CHOLESTEROL AND CHOLESTEROL ESTER

Transport and metabolism In the pregnant *rat* fed deuterated cholesterol the cholesterol reaches fetal tissues (82) In the *rat* about 80 percent of the placental cholesterol is derived from the maternal circulation and about 20 percent from cholesterol synthesized in the fetus or placenta. In the *rat* fetus the percent of cholesterol derived from the maternal circulation decreases from about 50 to 70 per cent at twelve to thirteen days of gestation to 15 to 20 per cent at the twentieth day of gestation (83) Similar results are reported with *rabbits* and *guinea pigs* In the *guinea pig* when the mother is fed a cholesterol free diet 20 to 24 per cent of the fetal serum cholesterol is derived from the mother When the mother s diet contained cholesterol 52 to 65 per cent of the fetal serum cholesterol was derived from the mother In both cases the newborn *guinea pig s* circulating level of cholesterol was the same (84) This is a striking example of the fetal control of circulating lipid levels in the presence of varying degrees of placental transport. It also demonstrates the error in presuming no placental transport when maternal and fetal circulating lipid levels show no correlation

In these studies no data are presented regarding the transfer of cholesterol esters. In the human maternal circulation one source of cholesterol esters is the enzymatic transfer of a fatty acid from lecithin to cholesterol (85) If cholesterol esters do not cross the placenta, the rate of this transesterification reaction may determine how much free cholesterol is available for transfer The transesterification reaction occurs also in the newborn infant's blood (86) This is one possible explanation of the higher relative per cent of arachidonic acid in umbilical cord cholesterol esters. When absolute levels of individual cholesterol esters are measured, it is found that the ratio of fetal to maternal cholesteryl arachidonate is greater in term than in premature infants (1?) The cause of this variation with gestational age is unknown.

In placental tissue cholesterol is synthesized *de novo* from acetate and mevalonate. However the synthesis of cholesterol is minimal compared to other sterols (87) Placental tissue will also form cholesterol esters from fatty acids and endogenous cholesterol (76 88) Since the free fatty acid pool of the placenta contains a high relative per cent of arachidonic acid (see Table 2) cholesterol esters formed in the placenta should contain relatively large amounts of arachidonic acid. As can be seen in Table 5 placental tissue falls between maternal and fetal blood in its relative per cent of arachidonic acid. These data do not allow any conclusions about the origin of fetal cholesterol esters. *Apparently cholesterol esters are not hydrolyzed* by the placenta (76)

Summary (see Fig. 3) It seems probable that cholesterol crosses from the maternal to the fetal circulation. No information about cholesterol esters is available. In placental tissue cholesterol can be synthesized *de novo* and then esterified with a fatty acid. It is unknown if the cholesterol esters formed in the placenta will enter the fetal circulation Cholesterol esters are apparently not hydrolyzed in placental tissue. In the maternal and fetal serum cholesterol esters are formed by the transfer of a fatty acid from lecithin to cholesterol.

PHOSPHOLIPIDS

Transport and metabolism. In the pregnant *rat* injected with labelled phospholipids small amounts of radioactivity are found in the fetal phospholipids (16) In *rabbits* similarly treated the

placenta takes up maternal circulating phospholipids and apparently they are not passed to the fetus (89)

In *sheep* there is a close resemblance in the exogenous fatty acid composition of maternal and fetal phospholipids which suggests the possibility of direct transfer across the placenta (71) The fatty acid patterns in human tissues are presented in Tables 6 and 7 It is noteworthy that, in the fatty acids of the lecithin fraction of perfused placenta and chorion laeve, the fetal pattern of relatively high values of arachidonic acid and low values of linoleic acid is present (see Table 6) This may indicate that the difference in maternal and fetal arachidonic acid metabolism is established at the placenta. It is interesting to speculate that the difference between the mother and fetus in the phospholipid fatty acid pattern represents selective fatty acid transport across the placenta as phospholipid esters In studies describing the

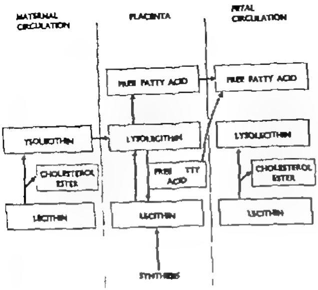

Fig. 4

decrease in maternal lysolecithin during pregnancy it is suggested that the human placenta may remove lysolecithin from the circulation (26). In placental tissue lysolecithin is esterified with a fatty acid to form lecithin (90). This enzyme is known, in other tissues, to preferentially esterify the more unsaturated fatty acids to form lecithin (91). Therefore the specificity of this enzyme may explain the high relative per cent of arachidonic acid in placental tissue. In the *rat* maternal circulating lysolecithin is removed from the circulation by the placenta and esterified to placental lecithin (92). If the lecithin so formed enters the fetal circulation an explanation would be provided for the high relative per cent of fetal lecithin arachidonic acid. However in the pregnant rat infused with P^{32} labelled lysolecithin no radioactivity is found in the fetus (92). Alternatively if the lecithin formed in the placenta were to release its fatty acid at the fetal side of the syncytial cell, the transport of individual fatty acids as phospholipid esters would be complete. If this cycle occurs there should be measurable lecithinase activity in placental cells. Minimal lecithinase activity is reported in the *rat* placenta (93), but none is found in the human placenta (94). Therefore transport of fatty acids to the fetus as phospholipid esters remains doubtful. These investigations should be extended to the ethanolamine and serine phospholipids.

Phospholipids are synthesized in the placenta as evidenced by the incorporation of P^{32} into all phospholipid fractions in incubations utilizing placental tissue slices. This incorporation is reportedly stimulated by the addition of estradiol to the incubation (95). In placental homogenates of twenty week old placentas, as contrasted to term placentas, no phospholipid is synthesized from C^{14} acetate (96). In the *rat* the incorporation of P^{32} into lecithin, lysolecithin, and phosphatidylethanolamine increases markedly as gestation progresses (97). This again suggests a possible dependency on maternal lipids in early pregnancy.

It should be mentioned that several authors studying the transport of amino acids across the rat placenta have described a phosphatido-peptide fraction in the placenta which may be involved in this transport (98, 99). These findings merit further study.

Summary (see Fig. 4). It is probable that intact phospholipids enter the placenta from the maternal circulation but do not pass directly into the fetal circulation. Maternal lysolecithin may well be the precursor of placental lecithin. The fate of lecithin synthesized in the placenta is unknown. The possibility of it acting as a specific fatty acid carrier to the fetal circulation is doubtful since the hydrolysis of lecithin apparently doesn't occur in placental tissue.

decrease in maternal lysolecithin during pregnancy it is suggested that the human placenta may remove lysolecithin from the circulation (26) In placental tissue lysolecithin is esterified with a fatty acid to form lecithin (90). This enzyme is known, in other tissues, to preferentially esterify the more unsaturated fatty acids to form lecithin (91). Therefore the specificity of this enzyme may explain the high relative per cent of arachidonic acid in placental tissue. In the *rat* maternal circulating lysolecithin is removed from the circulation by the placenta and esterified to placental lecithin (92). If the lecithin so formed enters the fetal circulation an explanation would be provided for the high relative per cent of fetal lecithin arachidonic acid However in the pregnant *rat* infused with P^{32} labelled lysolecithin no radioactivity is found in the fetus (92). Alternatively if the lecithin formed in the placenta were to release its fatty acid in the fetal side of the syncytial cell, the transport of individual fatty acids as phospholipid esters would be complete. If this cycle occurs there should be measurable lecithinase activity in placental cells. Minimal lecithinase activity is reported in the *rat* placenta (93), but none is found in the human placenta (94). Therefore transport of fatty acids to the fetus as phospholipid esters remains doubtful. These investigations should be extended to the ethanolamine and serine phospholipids.

Phospholipids are synthesized in the placenta as evidenced by the incorporation of P^{32} into all phospholipid fractions in incubations utilizing placental tissue slices. This incorporation is reportedly stimulated by the addition of estradiol to the incubation (95). In placental homogenates of twenty week old placentas, as contrasted to term placentas, no phospholipid is synthesized from C acetate (96). In the *rat* the incorporation of P^{32} into lecithin, lysolecithin, and phosphatidyl ethanolamine increases markedly as gestation progresses (97) This again suggests a possible dependency on maternal lipids in early pregnancy

It should be mentioned that several authors, studying the transport of amino acids across the *rat* placenta have described a phosphatido-peptide fraction in the placenta which may be involved in this transport (98 99) These findings merit further study

Summary (see Fig. 4). It is probable that intact phospholipids enter the placenta from the maternal circulation but do not pass directly into the fetal circulation. Maternal lysolecithin may well be the precourser of placental lecithin. The fate of lecithin synthesized in the placenta is unknown. The possibility of it acting as a specific fatty acid carrier to the fetal circulation is doubtful since the hydrolysis of lecithin apparently doesn't occur in placental tissue.

CORRELATION OF LIPID METABOLISM TO PERINATAL PHYSIOLOGY

Maternal diseases Toxemia and diabetes, perhaps because of the morphological changes in the placenta, have been repeatedly studied with regard to changes in maternal fetal and placental lipids. In general consistent abnormalities have not been found.

In toxemia changes in maternal lipids (37 100 101 102) placental lipids (3 103 194 105) and fetal lipids (46) have been reported. Other studies report no change (49 106 107) The reported changes are not consistent from report to report and in the most recent analysis the only significant difference is an increase in placental triglycerides which remains unexplained (3) In an excellent review it is pointed out that variables other than the toxemic process may affect lipid levels in toxemia. Among these are the administration of glucose and changes in plasma volume (108) The investigation of placental lipid metabolic routes in abnormal states has hardly begun. Reportedly the synthesis of phospholipids from C^{14} acetate by placental tissue does not occur in severe toxemia (96)

An interesting speculation regarding toxemia is *that the placental release of phosphatidylethanol* amine and phosphatidylserine into the maternal circulation may lead to intravascular coagulation accounting for the lesions seen in the maternal liver kidney and brain (108)

At the present time there is *little indication* of abnormal lipid metabolism or transport occurring in much less causing, toxemia.

In diabetes changes in maternal lipids (109 110) and fetal lipids (109 110 111) have been reported, whereas other studies on the placental lipids (112) newborn adipose tissue lipids (60), and umbilical cord blood free fatty acid levels in prediabetic progeny (49) *are reported as normal* The lack of similar analyses between studies and the relatively small number of samples in most studies make it impossible to draw any conclusions.

There is however one common finding! Diabetic progeny do not respond after birth with as marked an early rise in free fatty acids (10, 36 54) It is suggested that this results from a state of hyperinsulinism in the infant (10) or low levels of growth hormone (113) However no explanation is proven.

Onset of labor In *rabbits*, dipalmitoyl lecithin enhances the frequency and amplitude of uterine contractions (114) Infusions of cephalin are also reported to increase labour activity in humans (115) Another study reports isolating from human placentas a fatty acid (felt to be arachidonate) which stimulates smooth muscle contraction (116) This presumed fatty acid and its *activity is also found in amniotic fluid* (117) These studies give rise to the fascinating speculation that the placental metabolism of arachidonate and its precoursers could be related to the onset of normal or abnormal labor

Perinatal free fatty acid metabolism. In trying to explain the apparent lack of mobilization of free fatty acids in diabetic progeny we are led into the puzzling area of lipid metabolism in the infant before and after birth. It has long been stated that *in utero* the chief source of fetal energy is glucose and that lipids are not catabolized for energy The arguments for this presumption are the low levels of free fatty acids (118), glycerol (50) and ketones (55) at birth as well as the characteristically high respiratory quotient of the newborn (119)

That this is not necessarily the case at all times *in all gestations is suggested by several reports.* The oxidation of octanoic acid to acetoacetate has been demonstrated in the fetal liver (1‿0) and this capability in the placenta of different gestational ages should be investigated. An increase in *umbilical cord blood free fatty acids is described* in fetuses hypoxemic for about six hours as compared to those hypoxemic for about 2 1/ hours before birth (121) An elevation of the fetal/maternal ketone body ratio in the umbilical cord blood of toxemic offspring suggests prenatal fat catabolism (122). If free fatty acids are mobilized and oxidized before birth the question is if they *arise from the fetal adipose tissue or from the placenta.*

Recently it has been suggested that maternal hypoxia decreases the placental transport of glucose (123) When this occurs does the fetus mobilize free fatty acids as an energy source? Presumably in cases of intrauterine growth failure the situation of relative hypoxia and poor placental transport has occurred. At birth hypotrophic infants have low umbilical cord blood glucose levels but normal free fatty acid levels. This is followed by an accentuated free fatty acid rise after birth

(124) This would seem to indicate no free fatty acid mobilization before birth in these cases. Does the fetus respond to stimuli for free fatty acid mobilization? In the fetal *lamb* the free fatty acid response to intravascular infusions of adrenaline is very small and increases gradually after birth (125). From these data it appears that free fatty acid mobilization in the normal fetus is minimal.

After birth, the rise in free fatty acids in normal infants correlates with a fall in blood glucose (46, 126) and may be prevented by glucose administration (126). That this response is mediated by the sympathetic nervous system is suggested in newborn *lambs* since the intravenous injection of hexamethonium inhibits the free fatty acid rise (127).

Lipolysis occurs in infant adipose tissue most rapidly in the first few hours after birth and is least affected by the addition of glucose in the first fifteen hours of life. This factor distinguishes lipolysis in newborn adipose tissue from that process in the more mature infant's adipose tissue (128). Also, measuring the incorporation of C[14] palmitate into newborn adipose triglycerides there is reported not only an elevated level of diglyceride in this tissue but the incorporation of C[14] into that is probably a 1,3 diglyceride not found in adults (129). Obviously more investigation is needed in newborn adipose tissue metabolism.

The normal postpartum rise in the newborn infants free fatty acids is absent in diabetic offspring, as previously mentioned, delayed onset of respiration (46), prenatal maternal-fetal circulatory disturbances in *sheep* (130), and in some premature infants (54). It is suggested that the postnatal change in plasma free fatty acids may provide measure of the total body response to postnatal metabolic demands (130).

The decreased fatty acid response of premature infants (54) and diabetic progeny and the close relation of these two situations to hyaline membrane disease suggest an interesting area of study. If pulmonary surfactant is synthesized utilizing circulating free fatty acids, as is apparently the case in fetal *lambs* (131) and if the amount of surfactant is related to the occurrence of hyaline membrane disease (which is unknown), then a mechanism for the development of this disease is apparent.

No explanations for these variations from normal have been proven. However it does appear that perinatal free fatty acid metabolism may reflect some of the prenatal stresses which are currently so difficult to quantitate. This should be a rewarding area of research.

Prenatal essential fatty acid deficiency. A maternal diet deficient in the essential fatty acids or the inadequate transport of these fatty acids across the placenta could be expected to affect intrauterine growth. In newborn *rats* the birth weight and tissue content of linoleic acid is markedly decreased when the mother is fed a fat deficient diet (13). Also the dermatologic signs of essential fatty acid deficiency occur rapidly if the offspring receive a diet deficient in linoleic acid (133). In human infants demonstrating intrauterine growth failure analyses of placental and fetal tissue lipids are not now available and would be interesting.

SUMMARY

The more recent animal studies reveal the maternal origin of many placental and fetal lipids. In most studies the degree of transport across the placenta and the degree of fetal or placental synthesis of lipids varies with gestational age. Apparently earlier in pregnancy there is more dependence on maternal lipids to provide placental and fetal lipids. In most lipid classes studied the placenta has the capability of altering those lipids presented to it by selective transport and interconversions. Also, most lipid classes are synthesized *de novo* in the placenta.

This review of available information illustrates the many difficulties in describing placental lipid metabolism and transport. The first of these is the extrapolation of data from any other species to man. We hope that increased sophistication in the use of placental perfusion and in the preservation of human placental tissue will lead to the determination of the transport mechanisms in man as well as in other animals. Secondly composition studies are of value only in that they point the direction in which metabolic studies should proceed. The third problem is that the *in vitro* metabolic studies, which tell us what reactions may occur in placental tissue, are not applicable to the *in vivo* situation, since the magnitude of these reactions is unknown. This information can come only from the perfusion of the placenta with the substrates in question. Finally it appears

CORRELATION OF LIPID METABOLISM TO PERINATAL PHYSIOLOGY

Maternal diseases Toxemia and diabetes, perhaps because of the morphological changes in the placenta, have been repeatedly studied with regard to changes in maternal fetal, and placental lipids. In general consistent abnormalities have not been found

In toxemia changes in maternal lipids (37 100 101 102) placental lipids (3 103 194 105) and fetal lipids (46) have been reported. Other studies report no change (49 106 107) The reported changes are not consistent from report to report and in the most recent analysis the only significant difference is an increase in placental triglycerides which remains unexplained (3) In an excellent review it is pointed out that variables other than the toxemic process may affect lipid levels in toxemia. Among these are the administration of glucose and changes in plasma volume (108) The investigation of placental lipid metabolic routes in abnormal states has hardly begun Reportedly the synthesis of phospholipids from C^{14} acetate by placental tissue does not occur in severe toxemia (96)

An interesting speculation regarding toxemia is that the placental release of phosphatidylethanolamine and phosphatidylserine into the maternal circulation may lead to intravascular coagulation accounting for the lesions seen in the maternal liver kidney and brain (108).

At the present time there is little indication of abnormal lipid metabolism or transport occurring in much less causing, toxemia.

In diabetes changes in maternal lipids (109 110) and fetal lipids (109 110 111) have been reported, whereas other studies on the placental lipids (112) newborn adipose tissue lipids (60) and umbilical cord blood free fatty acid levels in prediabetic progeny (49) are reported as normal The lack of similar analyses between studies and the relatively small number of samples in most studies make it impossible to draw any conclusions.

There is however one common finding' Diabetic progeny do not respond after birth with as marked an early rise in free fatty acids (10 36, 54) It is suggested that this results from a state *of hyperinsulinism in the infant (10) or low levels* of growth hormone (113) However no explanation is proven

Onset of labor In *rabbits*, dipalmitoyl lecithin enhances the frequency and amplitude of uterine contractions (114) Infusions of cephalin are also *reported to increase labour activity in humans* (115) Another study reports isolating from human placentas a fatty acid (felt to be arachidonate) which stimulates smooth muscle contraction (116) This *presumed fatty acid and its* activity is also found in amniotic fluid (117) These studies give rise to the fascinating speculation that the placental metabolism of arachidonate and its precoursers could be *related to the onset of normal* or abnormal labor

Perinatal free fatty acid metabolism In trying to explain the apparent lack of mobilization of free fatty acids in diabetic progeny we are led into the puzzling area of lipid metabolism in the infant before and after birth It has long been stated that *in utero* the chief source of fetal energy is glucose and that lipids are not catabolized for energy The arguments for this presumption are the low levels of free fatty acids (118) glycerol (50), and ketones (55) at birth, as well as the characteristically high respiratory quotient of the newborn (119)

That this is not necessarily the case at all times in all gestations is suggested by several reports. The oxidation of octanoic acid to acetoacetate has been demonstrated in the fetal liver (120) and this capability in the placenta of different gestational ages should be investigated. An increase in umbilical cord blood free fatty acids is described in fetuses hypoxemic for about six hours as compared to those hypoxemic for about $2^1/_2$ hours before birth (121) An elevation of the fetal/maternal ketone body ratio in the umbilical cord blood of toxemic offspring suggests prenatal fat catabolism (122) If free fatty acids are mobilized and oxidized before birth the question is if they arise from the fetal adipose tissue or from the placenta.

Recently it has been suggested that maternal hypoxia decreases the placental transport of glucose (123) When this occurs does the fetus mobi*lize free fatty acids as an energy source?* Presumably in cases of intrauterine growth failure the situation of relative hypoxia and poor placental transport has occurred At birth hypotrophic in*fants have low umbilical cord blood glucose levels* but normal free fatty acid levels. This *is followed by an accentuated free fatty acid rise after birth*

(124) This would seem to indicate no free fatty acid mobilization before birth in these cases. Does the fetus respond to stimuli for free fatty acid mobilization? In the fetal *lamb* the free fatty acid response to intravascular infusions of adrenaline is very small and increases gradually after birth (125). From these data it appears that free fatty acid mobilization in the normal fetus is minimal.

After birth, the rise in free fatty acids in normal *infants* correlates with a fall in blood glucose (46, 126) and may be prevented by glucose administration (126). That this response is mediated by the sympathetic nervous system is suggested in newborn *lambs* since the intravenous injection of hexamethonium inhibits the free fatty acid rise (127).

Lipolysis occurs in infant adipose tissue most rapidly in the first few hours after birth and is least affected by the addition of glucose in the first fifteen hours of life. This factor distinguishes lipolysis in newborn adipose tissue from that process in the more mature infant's adipose tissue (128). Also, measuring the incorporation of C^{14} palmitate into newborn adipose triglycerides there is reported not only an elevated level of digly ceride in this tissue but the incorporation of C into that is probably a 1,3 diglyceride not found in adults (129). Obviously more investigation is needed in newborn adipose tissue metabolism.

The normal postpartum rise in the newborn infants free fatty acids is absent in diabetic offspring, as previously mentioned, delayed onset of respiration (46), prenatal maternal-fetal circulatory disturbances in *sheep* (130), and in some premature infants (54). It is suggested that the postnatal change in plasma free fatty acids may provide a measure of the total body response to postnatal metabolic demands (130).

The decreased fatty acid response of premature infants (54) and diabetic progeny and the close relation of these two situations to hyaline membrane disease suggest an interesting area of study. If pulmonary surfactant is synthesized utilizing circulating free fatty acids, as is apparently the case in fetal *lamb* (131), and if the amount of surfactant is related to the occurrence of hyaline membrane disease (which is unknown), then mechanism for the development of this disease is apparent.

No explanations for these variations from normal has been proven. However it does appear that perinatal free fatty acid metabolism may reflect some of the prenatal stresses which are currently so difficult to quantitate. This should be a rewarding area of research.

Prenatal essential fatty acid deficiency. A maternal diet deficient in the essential fatty acids or the inadequate transport of these fatty acids across the placenta could be expected to affect intrauterine growth. In newborn *rats* the birth weight and tissue content of linoleic acid is markedly decreased when the mother is fed a fat deficient diet (132). Also the dermatologic signs of essential fatty acid deficiency occur rapidly if the offspring receive a diet deficient in linoleic acid (133). In human infants demonstrating intrauterine growth failure analyses of placental and fetal tissue lipids are not now available and would be interesting.

SUMMARY

The more recent animal studies reveal the maternal origin of many placental and fetal lipids. In most studies the degree of transport across the placenta and the degree of fetal or placental synthesis of lipids varies with gestational age. Apparently earlier in pregnancy there is more dependence on maternal lipids to provide placental and fetal lipids. In most lipid classes studied the placenta has the capability of altering those lipids presented to it by selective transport and interconversions. Also, most lipid classes are synthesized *de novo* in the placenta.

This review of available information illustrates the many difficulties in describing placental lipid metabolism and transport. The first of these is the extrapolation of data from any other species to man. We hope that increased sophistication in the use of placental perfusion and in the preservation of human placental tissue will lead to the determination of the transport mechanisms in man as well as in other animals. Secondly composition studies are of value only in that they point the direction in which metabolic studies should proceed. The third problem is that the *in vitro* metabolic studies, which tell us what reactions may occur in placental tissue, are not applicable to the *in vivo* situation, since the magnitude of these reactions is unknown. This information can come only from the perfusion of the placenta with the substrates in question. Finally it appears

that the correlation of placental lipids to maternal fetal disease is not going to be easily shown. Perhaps the best approach is the definition of the functional capacity of the placenta to perform metabolic alterations of certain lipids. Then any alteration in this functional capacity of the placenta might well be more meaningful than an alteration in the lipid pattern of the placenta in disease states. In all the studies to be performed, a great need exists for the determination of composition and metabolic pathways in relationship to the time of gestation. Studies should be done at different periods of gestation for both the metabolism and transport of lipids appears to vary with gestational age

ACKNOWLEDGEMENTS

This investigation was supported in part by funds from a Public Health Research Grant, Number HD 02675 from the National Institute of Child Health and Human Development, and from a Public Health Research Grant, Number AM 09758, from the National Institute of Arthritis and Metabolic Diseases, and by a contract with the Ohio Department of Health, Maternal and Child Health Division.

Our appreciation is expressed to Miss Laura Osbourne, of the Health Center Library for performing our MEDLAR literature search and to Mrs. Marion Renwick for the preparation of the manuscript.

Address. (A.F.R.) Department of Pediatrics, Division of Neonatology The Ohio State University Hospital, Columbus, Ohio 43210

Clinical study of human growth hormone on children and newborn infants

In the present study special interest has been directed to the chromatoelectrophoretic method described by Glick et al. (1963). This method was originally published for insulin by Berson et al. (1956). Small amounts of HGH are strongly adsorbed on a special paper whilst that bound to antibody moves towards the anode with the gamma globulins. The separation must be carried out at 4° C since the heat generated by the current may cause dissociation of the labeled HGH at higher temperatures. Yalow and Berson (1964) however showed that the flow of buffer along a strip may be effected very simply by evaporation and that method has been used in this study. The method is described in detail and the influence of damage to the labeled HGH has been studied. Special attention is given to the application of the method on neonatal plasma.

CHAPTER I

Introduction

Until recently the assay of hormones in blood was achieved in most instances by bio-assay techniques. A number of bio-assays have been suggested for human growth hormone (HGH) (Evans and Simpson 1931 Marx et al. 1942 and Evans et al 1943) However the specificity and precision of all the biological methods were insufficient for them to be of clinical use. Read and Bryan (1960) adapted the haemagglutination inhibition test for HGH which proved to be satisfactory for the quantitative determination of HGH in highly purified anterior pituitary extracts but was unreliable when applied to human serum because of nonspecific factors in the serum The radioimmunological method for insulin was introduced in 1959 by Berson and Yalow and was applied to HGH independently by Hunter and Greenwood (1962 a) Utiger et al (1962) and Glick et al (1963) The principle of the method depends on the competition between radioactively labeled and unlabeled hormone for the specific binding sites of the antibody (Fig 1) The higher the concentration of the unlabeled hormone the less radioactively labeled hormone will be bound to the antibody After separating the bound from the free hormone the fractions can be measured. Using suitably small, known quantities of unlabeled hormone a standard curve is prepared. The concentration of hormone in unknown samples can be read off the curve directly

In the radioimmunoassay of hormones in blood it is customarily assumed that labeled

Fig 1 Principle of radioimmunoassay

and unlabeled hormones behave identically that the circulating hormone is chemically and immunologically identical with the standard hormone preparation that the amount of hormone bound by the antibody is independent of the concentration of the hormone and that different antisera made against a particular antigen will give a similar quantitative response in the immunoassay system.

The HGH used for immunoassay has been prepared by several different methods (Li and Papkoff 1956 Raben 1959 Roos et al. 1963) and there seems to be some differences in homogeneity between the preparations. It would be more precise to use the term immunoreactive growth hormone for HGH amounts estimated with radioimmunoassays. This term however is inconvenient to use in practice and HGH is substituted in the following for immunoreactive growth hormone.

The various methods available for radioimmunoassay of HGH differ mainly in the technique used to separate free from antibody bound hormone A perfect system would show no labeled antigen in the bound fraction in the absence of antibody and 100 per cent of the labeled antigen in the 'bound' fraction after incubation with excess antibody A number of methods for separation have been published among them by electrophoresis on cellulose acetate membranes, (Hunter and Greenwood 1964) polyacrylamide gel electrophoresis (Fitschen 1964) chromatoelectrophoresis (Glick et al 1963) ion-exchange-resin (Lazarus and Young 1966) adsorption on charcoal (Lau et al 1966) and by using a second antibody to precipitate the antibody bound hormone (Utiger et al. 1962 Hartog et al. 1964 a, Ceraci et al. 1966)

In the present study special interest has been directed to the chromatoelectrophoretic method described by Glick et al. (1963). This method was originally published for insulin by Berson et al. (1956). Small amounts of HGH are strongly adsorbed on a special paper whilst that bound to antibody moves towards the anode with the gamma globulins. The separation must be carried out at 4°C since the heat generated by the current may cause dissociation of the labeled HGH at higher temperatures. Yalow and Berson (1964) however showed that the flow of buffer along a strip may be effected very simply by evaporation and that method has been used in this study. The method is described in detail and the influence of damage to the labeled HGH has been studied. Special attention is given to the application of the method on neonatal plasma.

CHAPTER II

Analytical procedure for a radioimmunoassay of human growth hormone

In collaboration with Paul Roos and
Jan I Thorell

Source of human growth hormone

HGH prepared by the method of Roos et al (1963) was used throughout the study without further purification for immunisation for labeling and as standard HGH. HGH I C.R F batch 6 peak II contributed by Dr F C. Greenwood, London and NIH-GH HS 612 A obtained from Dr A. Wilhelmi, Atlanta Georgia have been used for methodological studies.

During the study six different Roos preparations have been used for immunoassay purposes. For the preparation of the guinea pig antiserum to HGH GF 19 was used. As standard solutions 1963 — 4/1965 GF 25 26 3 were used, later GF 29 2 and for methodological studies, GF 126 For labeling purposes no preparation older than 8 months was used as it was noted that prolonged storage resulted in a decreased yield in the labeling procedure. The following preparations were labeled GF 25 26 3 29 2, 39 2, 48 53 and for methodological studies GF 57 and GF 60 The preparations have been lyophylised and stored at +4°C. Labeled growth hormone was prepared every 3—4 weeks. Before a new batch of growth hormone was used for labeling its immunological activity was compared with the current laboratory standard. Furthermore the old and the new batches were labeled simultaneously to compare the immunological activity of the labeled preparations. No difference could be detected between the preparations except for preparations 57 and 60

Preparation of ^{131}I labeled growth hormone

The modification of Benerjee and Gibson (1962) of the original method by Hunter and Greenwood (1962 b) was used for labeling The carrier free sodium (^{131}I) iodide was used within 36 hours of the commercial preparation A 5μg HGH sample was shaken 60 sec with 2 mC sodium iodide and 30 μg chloramine-T as oxidizing agent. The reaction was stopped by adding 200 μg sodium meta bisulfite. All reagents except ^{131}I were dissolved in buffer 1 For buffer solutions see below

The separation of ^{131}I labeled HGH from the reaction mixture has been modified from the Banerjee-Gibson (1962) method and from that used by Hunter and Greenwood (1962 b) The mixture was passed through a column of Sephadex G 50 (Pharmacia, Uppsala Sweden) the column measuring 1 8 cm in diameter and containing 10 g of dry gel. The gel was allowed to swell in barbital buffer 2 in a beaker for 24 hours before packing of the column. To minimize adsorption onto the gel 100 mg *crystalline serum albumin* was passed through the column followed by a minimum of two column volumes of buffer 2 prior to

the application of the reaction mixture. The columns were run gravimetrically at a flow rate of approximately 3 ml/5 minutes. Fractions of $1^1/_2$ ml were collected manually. To the fractions 0.05 ml of 7 % bovine serum albumin in buffer 3 was immediately added in order to prevent radiation damage. They were then counted in a well-type scintillation counter (Philips PW 4119) with suitable shielding.

The radioactivity was obtained in 3 peaks (Fig. 2). The approximate yield of labeling was calculated by the relation between the salt peak and the protein containing peaks.

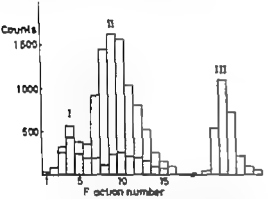

Fig. 2. Gel filtration of reaction mixture of ¹³¹I-labeled growth hormone. Counts are arbitrary radioactive units. ... indicates amount of damaged hormone. The best fractions are in the front part of the second peak. In the experiments fraction 8 was used for immunoassay. Peak III is the radioactive I 131 salt peak.

All fractions were tested for degradation products (damaged HGH) in the following way: 10 µl of gel filtration fractions were mixed with 100 µl of a 7 % bovine serum albumin solution in buffer 2 and 500 µl of buffer 3. Fifty µl of this mixture was applied on a moistened 2×25 cm paper strip (Whatman 3 MC). A minimal amount of Brom Cresol green was dropped at the application line for flow identification. The paper strips were suspended horizontally with one end immersed in buffer 2. Intact HGH is adsorbed at the application line while the degradation products migrate with the carrier proteins in the buffer flow to the center of the paper strip. This modification of the originally chromato-electrophoretic technique of Berson et al (1956) was chosen since it was shown by Yalow and Berson (1964) that the flow of buffer along the strip may be effected very simple by evaporation. If antibody is added the antibody-bound growth hormone and the damaged labeled hormone move together in the buffer flow chromatography as well as in the chromato-electrophoretic system. Flow chromatography was performed at room temperature not exceeding 20 C using cooled buffer 2. The procedure was stopped after about 30 minutes using the front of the Brom Cresol green as indicator for adequate separation. After drying the strips at 120 C they were scanned with a Geiger Müller tube using a slit of 2 mm. The separation is shown in Fig. 3.

CHAPTER II

Analytical procedure for a radioimmunoassay of human growth hormone

In collaboration with Paul Roos* and Jan I Thorell**

Source of human growth hormone

HGH prepared by the method of Roos et al (1963) was used throughout the study without further purification for immunisation for labeling and as standard HGH. HGH I C.R.F batch 6 peak II contributed by Dr F C. Greenwood London and NIH GH HS 612 A obtained from Dr A Wilhelmi Atlanta, Georgia have been used for methodological studies.

During the study six different Roos preparations have been used for immunoassay purposes. For the preparation of the guinea pig antiserum to HGH GF 19 was used. As standard solutions 1963 — 4/1965 GF 25 26 3 were used, later GF 29 2 and for methodological studies, GF 126. For labeling purposes *no preparation older than 8 months was used,* as it was noted that prolonged storage resulted in a decreased yield in the labeling procedure. The following preparations were labeled GF 25 26 3, 29 2, 39 2, 48, 53 and for methodological studies GF 57 and GF 60. The preparations have been lyophylised and stored at +4 C. Labeled growth hormone *was prepared every 3—4 weeks. Before a new* batch of growth hormone was used for labeling its immunological activity was compared with the current laboratory standard. Furthermore the old and the new batches were labeled simultaneously to compare the immunological activity of the labeled preparations. No difference could be detected between the preparations except for preparations 57 and 60.

Preparation of ^{131}I labeled growth hormone

The modification of Benerjee and Gibson (1962) of the original method by Hunter and *Greenwood (1962 b) was used for labeling.* The carrier free sodium (^{131}I) iodide was used within 36 hours of the commercial preparation. A 5 µg HGH sample was shaken 60 sec with 2 mC sodium iodide and 30 µg chloramine-T as oxidizing agent. The reaction was stopped by adding 200 µg sodium meta bisulfite. All reagents except ^{131}I were *dissolved in buffer 1. For buffer solutions see* below.

The separation of ^{131}I labeled HGH from the reaction mixture has been modified from the Banerjee-Gibson (1962) method and from that used by Hunter and Greenwood (1962 b). The mixture was passed through a column of Sephadex G-50 (Pharmacia, Uppsala, Sweden) *the column measuring* 1.8 cm in diameter and containing 10 g of dry gel. The gel was allowed to swell in barbital buffer 2 in a beaker for 24 hours *before packing of the* column. To minimize adsorption onto the gel 100 mg crystalline serum albumin was passed through the column followed by a minimum of two column volumes of buffer 2 prior to

2. 50 µl plasma or various amounts of HGH-standard giving final concentrations of 0.1, 2, 10, 20, 50 and 100 ng HGH/ml.
3. Guinea pig antiserum to HGH, final dilution 1:500.000.
4. Buffer 3 used as diluent to a final incubation volume of 500 µl.

For the standard curve duplicate tubes were prepared for every concentration of standard HGH. For plasma samples triplicate tubes were prepared.

In order to enable calculation of the incubation damage an incubation mixture identical with the standard or unknown plasma sample, but without antibody, was prepared in duplicate for the standard curve and in triplicate for plasma from each patient. If there were more than 3 samples from the same patient the first and last samples were tested. The incubation mixture was mixed carefully after preparation and 24 hours later. It was kept at +4°C for 4 days.

Separation of free and antibody bound HGH

To every tube for the standard curve 50 µl of adult heparin plasma (from blood donors) was added as carrier protein. To the plasma samples 50 µl buffer 3 was added to keep identical volumes. After moderate shaking 2×125 µl was put on a 4×25 cm paper strip of Whatman 3 MC paper previously moistened with buffer 2. On the application site a minimal amount of Brom Cresol green was added as indicator. Flow chromatography was then performed at room temperature not exceeding 20 C, using buffer 2 that was kept at 4 C by adding pieces of the frozen buffer. The procedure was identical with that described for testing the labeled HGH fractions. The chromatography was stopped when the front had moved exactly 6 cm (after about 30 min.). This gave an adequate separation between the free HGH that was adsorbed at the application site and the antibody-bound HGH that moved with the protein. The strips were dried at 120 C and cut in two parts between application site and the moving proteins and the radioactivity measured. The control tubes (incubation mixture without antibody) were handled identically.

Calculation of standard curve

By this method it is possible to make an approximate correction for damaged HGH which in the buffer flow system moves with the protein and the antibody-bound HGH but has no antibody binding capacity. The calculation is made on the control samples (incubation mixture without antibody). If I is intact HGH measured at the application line and M is damaged HGH moving with the protein and the per cent damaged is K than $K = \frac{M}{M+I} \times 100$

The true $\frac{B}{B+F}$ ratio of a sample is, if F is the free HGH measured at the application point and B_t is antibody-bound and damaged HGH moving with the proteins

$$\frac{B - K\ (B_t+F)}{F+B - K\ (B_t+F)}$$

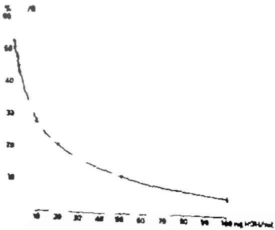

Fig. 4. Mean and S.D. of 10 consecutive standard curves plotted in linear diagram. Bar indicate S.D.

culated in the following way d = sum of counts of damaged HGH in all tubes with more than 100 counts in peaks I and II (Shadowed area in Fig 2) T = sum of counts in all tubes with more than 100 counts in peak I and II $D = \frac{d}{T} \times 100$ The total damaged fraction D was usually about 25 %. The tube with the least fraction of damage was used for the assay It was diluted in buffer 3 to a concentration of 10 ng/ml and kept at —20°C.

Human growth hormone standard

During the period 1963 to April 1965 a standard solution was prepared from Roos GF 25 26 3 Stock solutions in concentrations 1 10 and 50 ng/ml in buffer 3 were prepared and kept at —70°C. The amount sufficient for one month s use was kept at —20°C. An accident with the main part of the standard solutions made it necessary to prepare a new standard A freshly prepared Roos HGH GF 29 2 was diluted and stored as above Very careful tests with repeated standard curves could not reveal any differences in the immunological activity of the two preparations.

Guinea pig antiserum to HGH

Adult guinea pigs were injected subcutaneously three times with 1 mg of Roos GF 19 in Freunds complete adjuvant. The intervals between the injections were three weeks, the guinea pigs were bled by cardiac puncture one week after the last injection The serum and stock dilutions were kept at —70 C, amounts for one month s use, at — 20°C. Antiserum Ma 1 was used throughout the study This antiserum in antibody excess proportions completely bound ^{131}I HGH. The binding was fully prevented if the antibodies were saturated with unlabeled HGH.

Buffer solutions

1 For preparation of ^{131}I HGH 0.16 M borate buffer pH 8 0 2 For gel filtration and buffer flow chromatography 0 1 M Barbital buffer (LKB 3276) pH 8 6 3 For dilution of antibody and ^{131}I HGH for HGH standard solutions and as incubation diluent 0 1 M Barbital buffer (LKB 3276) with 0 25 % crystalline bovine serum albumin

Reagents and equipment

Indicator for buffer flow indentification 2 ml 0 1 M Barbital buffer (LKB 3276) pH 8 6 with 7 % crystalline bovine serum albumin and 2—3 grains of Brom Cresol green (Tetra brom-m-cresolsulfonephthalein)

Albumin Crystalline bovine serum albumin (BSA) was a gift from AB Kabi, Stockholm Sweden It was prepared by Armour and Co Eastbourne Sussex, England.

Incubation mixture

In a 5.5×1 0 glass tube a mixture of

1 0.2 ng ^{131}I HGH.

2. 50 µl plasma or various amounts of HGH-standard giving final concentrations of 0.1, 2, 10, 20, 50 and 100 ng HGH/ml.
3. Guinea pig antiserum to HGH, final dilution 1:500.000.
4. Buffer 3 used as diluent to a final incubation volume of 500 µl.

For the standard curve duplicate tubes were prepared for every concentration of standard HGH. For plasma samples triplicate tubes were prepared.

In order to enable calculation of the incubation damage an incubation mixture identical with the standard or unknown plasma sample, but without antibody, was prepared in duplicate for the standard curve and in triplicate for plasma from each patient. If there were more than 3 samples from the same patient the first and last samples were tested. The incubation mixture was mixed carefully after preparation and 24 hours later. It was kept at +4° C for 4 days.

Separation of free and antibody bound HGH

To every tube for the standard curve 50 µl of adult heparin plasma (from blood donors) was added as carrier protein. To the plasma samples 50 µl buffer 3 was added to keep identical volumes. After moderate shaking 2×125 µl was put on a 4×25 cm paper strip of Whatman 3 MC paper previously moistened with buffer 2. On the application site a minimal amount of Brom Cresol green was added as indicator. Flow chromatography was then performed at room temperature not exceeding 20° C, using buffer 2 that was kept at +4° C by adding pieces of the frozen buffer. The procedure was identical with that described for testing the labeled HGH fractions. The chromatography was stopped when the front had moved exactly 6 cm (after about 30 min.). This gave an adequate separation between the free HGH that was adsorbed at the application site and the antibody-bound HGH that moved with the protein. The strips were dried at 120°C and cut in two parts between application site and the moving proteins and the radioactivity measured. The control tubes (incubation mixture without antibody) were handled identically.

Calculation of standard curve

By this method it is possible to make an approximate correction for damaged HGH which in the buffer flow system moves with the protein and the antibody bound HGH but has no antibody binding capacity. The calculation is made on the control samples (incubation mixture without antibody). If I is intact HGH measured at the application line and M is damaged HGH moving with the protein and the per cent damaged is K than $K = \frac{M}{M+I} \times 100$

The true $\frac{B}{B+F}$ ratio of a sample is, if F is the free HGH measured at the application point and B_t is antibody-bound and damaged HGH moving with the proteins

$$\frac{B_t - K\ (B_t + F)}{F + B - K\ (B_t + F)}$$

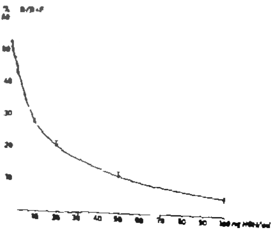

Fig. 4. Mean and S.D. of 10 consecutive standard curves plotted in linear diagram. Bars indicate S.D.

culated in the following way d = sum of counts of damaged HGH in all tubes with more than 100 counts in peaks I and II (Shadowed area in Fig 2) T = sum of counts in all tubes with more than 100 counts in peak I and II $D = \frac{d}{T} \times 100$ The total damaged fraction D was usually about 25 %. The tube with the least fraction of damage was used for the assay It was diluted in buffer 3 to a concentration of 10 ng/ml and kept at —20°C.

Human growth hormone standard

During the period 1963 to April 1965 a standard solution was prepared from Roos GF 25 26 3 Stock solutions in concentrations 1 10 and 50 ng/ml in buffer 3 were prepared and kept at —70°C. The amount sufficient for one month s use was kept at —20°C. An accident with the main part of the standard solutions made it necessary to prepare a new standard A freshly prepared Roos HGH GF 29 2 was diluted and stored as above. Very careful tests with repeated standard curves could not reveal any differences in the immunological activity of the two preparations.

Guinea pig antiserum to HGH

Adult guinea pigs were injected subcutaneously three times with 1 mg of Roos GF 19 in Freunds complete adjuvant. The intervals between the injections were three weeks the guinea pigs were bled by cardiac puncture one week after the last injection. The serum and stock dilutions were kept at —70°C, amounts for one month s use, at — 20 C. Antiserum Ma I was used throughout the study This antiserum in antibody excess proportions completely bound ^{131}I HGH The binding was fully prevented if the antibodies were saturated with unlabeled HGH.

Buffer solutions

1 For preparation of ^{131}I HGH 0 16 M borate buffer pH 8 0 2 For gel filtration and buffer flow chromatography 0 1 M Barbital buffer (LKB 3276) pH 8 6 3 For dilution of antibody and ^{131}I HGH for HGH standard solutions and as incubation diluent 0 1 M Barbital buffer (LKB 3276) with 0.25 % crystalline bovine serum albumin

Reagents and equipment

Indicator for buffer flow indentification 2 ml 0 1 M Barbital buffer (LKB 3276) pH 8 6 with 7 % crystalline bovine serum albumin and 2—3 grains of Brom Cresol green (*Tetra brom m-cresolsulfonephthalein*)

Albumin Crystalline bovine serum albumin (BSA) was a gift from AB Kabi Stockholm Sweden. It was prepared by Armour and Co Eastbourne, Sussex England.

^{131}Iodide Sodium ^{131}I carrier free (*IBS3*) The Radiochemical Centre, Amersham England.

Pipettes For pipetting labeled HGH HGH antibody and plasma into incubation tubes Hamilton microliter syringes with 100 µl capacity and 5 cm cemented needle and Chaney Adaptation (710—NCH) from Hamilton Company Whitteer Calif USA For HGH standards AGLA brand Micrometer Syringe Outfit from Burroughs Wellcome & Co London, England

Chromatography paper Whatman 3 MC. Two different batches without significant differences were used throughout the study (Four of six tested batches were not suitable)

Counting equipment Philips PW 4119 well type scintillation counter and Baird Atomic automatic sample changer

Incubation mixture

In a 5.5×1 0 glass tube a mixture of
1 0 2 ng ^{131}I HGH

2. 50 µl plasma or various amounts of HGH-standard giving final concentrations of 0.1, 2, 10, 20, 50 and 100 ng HGH/ml.
3. Guinea pig antiserum to HGH, final dilution 1 500.000
4. Buffer 3 used as diluent to a final incubation volume of 500 µl.

For the standard curve duplicate tubes were prepared for every concentration of standard HGH. For plasma samples triplicate tubes were prepared.

In order to enable calculation of the incubation damage an incubation mixture identical with the standard or unknown plasma sample, but without antibody was prepared in duplicate for the standard curve and in triplicate for plasma from each patient. If there were more than 3 samples from the same patient the first and last samples were tested. The incubation mixture was mixed carefully after preparation and 24 hours later It was kept at +4 C for 4 days.

Separation of free and antibody bound HGH

To every tube for the standard curve 50 µl of adult heparin plasma (from blood donors) was added as carrier protein. To the plasma samples 50 µl buffer 3 was added to keep identical volumes. After moderate shaking 2×125 µl was put on a 4×25 cm paper strip of Whatman 3 MC paper previously moistened with buffer 2. On the application site a minimal amount of Brom Cresol green was added as indicator. Flow chromatography was then performed at room temperature not exceeding 20°C, using buffer 2 that was kept at +4 C by adding pieces of the frozen buffer. The procedure was identical with that described for testing the labeled HGH fractions. The chromatography was stopped when the front had moved exactly 6 cm (after about 30 min.) This gave an adequate separation between the free HGH that was adsorbed at the application site and the antibody-bound HGH that moved with the protein. The strips were dried at 120 C and cut in two parts between application site and the moving proteins and the radioactivity measured. The control tubes (incubation mixture without antibody) were handled identically.

Calculation of standard curve

By this method it is possible to make an approximate correction for damaged HGH which in the buffer flow system moves with the protein and the antibody-bound HGH but has no antibody binding capacity. The calculation is made on the control samples (incubation mixture without antibody). If I is intact HGH measured at the application line and M is damaged HGH moving with the protein and the per cent damaged is K than $K = \frac{M}{M+I} \times 100$

The true $\frac{B}{B+F}$ ratio of a sample is, if F is the free HGH measured at the application point and B_1 is antibody-bound and damaged HGH moving with the proteins:

$$\frac{B_1 - K\ (B+F)}{F + B_1 - K\ (B_1+F)}$$

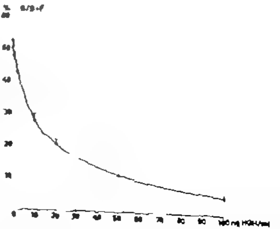

Fig. 4. Mean and S.D. of 10 consecutive standard curve plotted in linear diagram. Bars indicate S.D.

K varies between 10—30 % and if 35 % or more the precision of the method is markedly diminished In the standard curve the true $\frac{B}{B+F}$ ratio is expressed in per cent. The standard curve can be plotted in a linear system with per cent $\frac{B}{B+F}$ on the ordinate and the HGH concentrations on the abscissa, (Fig 4) It is, however more convenient to plot the curve in a semilogarithmic diagram (Fig 5) since the curve is nearly linear between 2 and 100 ng HGH/ml.

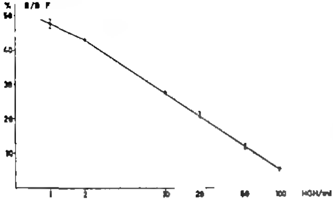

Fig 5 Mean and S.D of 10 consecutive standard curves plotted in a semilogarithmic diagram Bars indicate S D

Calculation of test sample

This was performed in the same way as the standards and the $\frac{B}{B+F}$ ratio was compared with the standard curve, plotted in the semilogarithmic system.

A standard curve and 25—35 test samples in triplicate and with controls as above can be analysed in one series. The laboratory routine was to prepare samples and run buffer flow chromatography twice a week

Methodological studies of the immunoassay for HGH

Effect of different HGH preparations as standard HGH

All HGH preparations used for assay routine are prepared by the method described by Roos et al. (1963) The preparations used are stated in chapter II. So far however no international standard preparation of HGH for immunoassay purpose is available. To compare the laboratory standard with other preparations the following experiments were performed. (November 1966)

HGH preparations studied were

1 Roos GF 6 prepared 1962 and kept lyophylised at +4 C.

2. Roos GF 29 2 our laboratory standard for immunoassay Stock solutions in buffer 3 and in concentration 1 10 and 50 ng/ml were prepared within a month after the preparation of the hormone and kept at —70 C No previously thawed samples were used as standards in these experiments.

3 A British HGH preparation (Imperial Cancer Research Fund batch 6 peak II) contributed by Dr F C. Greenwood. This sample was prepared 1964 and, since December 1964 was kept dissolved in buffer 3 and stored as Roos GF 29 2.

4 A lyophylised Wilhelmi preparation NIH —GH—HS 612 A.

The lyophylised preparations were dissolved in barbital buffer 3 one week before the experiment. The results are shown in Fig 6

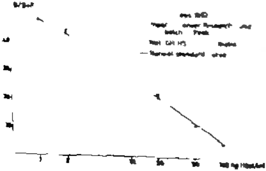

Fig 6 Standard curves with different HGH preparations

The Roos HGH consists of at least four different components when separated on column electrophoresis as shown in Fig. 7

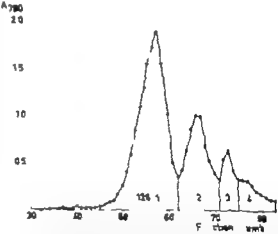

Fig. 7 Protein distribution from column electrophoresis at pH 8.6 of HGH obtained through gel filtration on Sephadex G-100.

These components have identical biological activity (Roos et al. 1963) and similar lactotrophic activity (Lions et al. 1966) The immunological activity of the four components has been studied in a second experiment. The fractions 126 1—4 were components of GF 29 2. The results in Fig. 8 indicate that fraction 126—4 which constitutes a minor

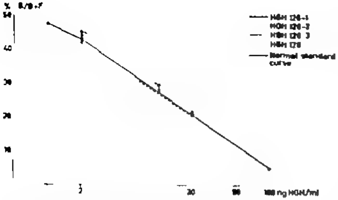

Fig 8 Immunological activity of four different electrophoretic components of GF 29 compared with normal standard curve of GF 29

portion has an immunological activity markedly lower than the other components.

From the first experiment it can be concluded that the HGH assay of a given sample can differ if compared with different standard preparations. The immunological activity of our laboratory standard is higher than the preparation used by Greenwood and slightly higher than the Wilhelmi preparation. From this it follows that our HGH values will be lower than those published by authors using one of the above mentioned preparations as standards This indicates the necessity of an international standard for HGH used for immunoassay The markedly low immunological activity of GF 6 (Fig 6) might be the result of the storage of the preparation but might even indicate that earlier Roos preparations were less active

The second experiment shows that available "clean growth hormone easily can be fractionated into different components and despite the fact that these components have identical biological activity the immunological activity varies From this it can be concluded that the immunological and biological sites of the HGH molecule are not completely identical Thus HGH preparations intended for clinical purposes must be tested not only for their immunological activity but for their biological activity as well

Separation of ^{131}I labeled HGH from reaction mixture

Initially the method of Hunter and Greenwood (1962 b) was tested The radioactivity was monitored in two peaks, the protein peak and the salt peak There was no apparent difference in the amount of degradation damage in the different tubes of the protein peak and since the degradation damage often exceeded 30 % a more proper separation was necessary Gelfiltration was chosen as a very mild method. Different amounts (2.1—17.5 g) of Sephadex G-50 and G-75 were tried in 1 8 cm diameter columns. The reaction mixture was diluted to a total volume of 2 ml and 0 5 ml was used for every column. The Sephadex used was allowed to swell in buffer 2 in a beaker for 24 hours, and following packing of the column 10 mg crystalline serum albumin per gram Sephadex in buffer 2 was run through the column to prevent adsorption of labeled protein. A minimum of two column volumes of buffer 2 was passed through the columns prior to the application of the reaction mixture. All columns were run gravimetrically the fractions were collected manually in volumes of 1.5 ml The results obtained in 2 different labeling procedures are shown in Table I

As seen in Fig. 9 a double protein peak is seen when 10 g or more of Sephadex G-50

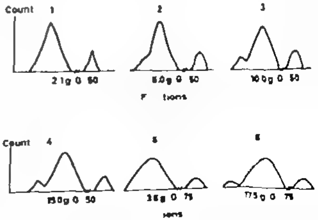

Fig 9 Approximate separation of labeling mixture by gel filtration on varying amounts of G 50 and G-75

TABLE I *Effect of variations in Sephadex separation of reaction mixture*

Mode of separation	Lengt of column in cm	Per cent damaged in best tube	Recovery of reaction mixture	Labeling
Sephadex G-50 2.1 g	10	27	[illegible] %	
Sephadex G-50 5 g	23	22	[illegible] %	1
Sephadex G-50 10 g	46	12	78 %	
Sephadex G-50 15 g	70	11	78 %	
Sephadex G-50 2.1 g	10	29	[illegible] %	
Sephadex G-50 10 g	46	12	77 %	2
Sephadex G-75 3.6 g	7	50	[illegible] %	
Sephadex G-75 17.5 g	35	19	79 %	

is used. There was no advantage in using more than 10 g G-50 or using G-75. The separation with 10 g G-50 was chosen, usually giving a labeled product with less than 15 % degradation damage in the best tube.

Some factors influencing the degradation damage

The problem of degradation products has been deal with by several authors (Yalow and Berson, 1964, Midgley 1966 and Glover et al. 1967) and is one of the main difficulties in the labeling procedure.

In our laboratory as in others the labeling procedure has failed in periods, the only variable being a new preparation of ^{131}I. Generally a bad labeling was characterized by a poor yield (less than 40 %) and a large amount of degradation products. Such preparations could not be used for assay purposes. It was early experienced that the ^{131}I had to be freshly prepared, thus it was normally used within 24 hours after the commercial preparation, and never later than 36 hours after the preparation.

For routine labeling lyophylised Roos GF 25, 26.3, 29.2, 39.2, 48 and 53 were used. No significant differences could be shown between the preparations used for the assay. The yield of the labeling procedure was usually between 60—90 % giving a specific activity of 240—330 μc/μg, the preparation containing less than 1 atom of iodide per molecule HGH.

Since the problem of degradation damage is more pronounced for HGH than for other polypeptide hormones it is conceivable that the HGH molecule is more susceptible than other polypeptides. However HGH is more heterogeneous than other hormones (Hunter 1965, Berson and Yalow 1966, Trygstad 1967). The heterogeneity of the Roos preparation has already been demonstrated (Fig 7). Furthermore it has been shown that lyophylising Roos preparations gives rise to further heterogeneity which may be due to polymerization (Hanston et al. 1966).

To determine whether differences in the storage conditions of Roos HGH alters the labeling product two different batches of HGH prepared by the same procedure were labeled. In one experiment a lyophylised and a frozen (in buffer 1) preparation of GF 57 were labeled simultaneously. In a second experiment GF 57 lyophylised and GF 60 never lyophylised nor frozen were labeled. The results are listed in Table II. The

is used. There was no advantage in using more than 10 g G-50 or using G 75. The separation with 10 g G-50 was chosen, usually giving a labeled product with less than 15 % degradation damage in the best tube.

Some factors influencing the degradation damage

The problem of degradation products has been dealt with by several authors (Yalow and Berson, 1964 Midgley 1966 and Glover et al. 1967) and is one of the main difficulties in the labeling procedure.

In our laboratory as in others the labeling procedure has failed in periods, the only variable being a new preparation of ¹³¹I. Generally a bad labeling was characterized by a poor yield (less than 40 %) and a large amount of degradation products. Such preparations could not be used for assay purposes. It was early experienced that the ¹³¹I had to be freshly prepared, thus it was normally used within 24 hours after the commercial preparation and never later than 36 hours after the preparation.

For routine labeling lyophylised Roos GF 25 26:3 29 2, 39 2 48 and 53 were used. No significant differences could be shown between the preparations used for the assay The yield of the labeling procedure was usually between 60—90 % giving a specific activity of 240—330 μc/μg, the preparation containing less than 1 atom of iodide per molecule HGH.

Since the problem of degradation damage is more pronounced for HGH than for other polypeptide hormones it is conceivable that the HGH molecule is more susceptible than other polypeptides. However HGH is more heterogeneous than other hormones (Hunter 1965 Berson and Yalow 1966, Trygstad 1967) The heterogeneity of the Roos preparation has already been demonstrated (Fig 7) Furthermore it has been shown that lyophylising Roos preparations gives rise to further heterogeneity which may be due to polymerization (Hansson et al. 1966)

To determine whether differences in the storage conditions of Roos HGH alters the labeling product two different batches of HGH prepared by the same procedure were labeled. In one experiment a lyophylised and a frozen (in buffer 1) preparation of GF 57 were labeled simultaneously In a second experiment GF 57 lyophylised and GF 60 never lyophylised nor frozen were labeled. The results are listed in Table II. The

is used. There was no advantage in using more than 10 g G-50 or using G-75. The separation with 10 g G-50 was chosen, usually giving a labeled product with less than 15 % degradation damage in the best tube.

Some factors influencing the degradation damage

The problem of degradation products has been dealt with by several authors (Yalow and Berson, 1964 Midgley 1966 and Glover et al. 1967) and is one of the main difficulties in the labeling procedure.

In our laboratory as in others the labeling procedure has failed in periods, the only variable being a new preparation of ^{131}I. Generally a bad labeling was characterized by a poor yield (less than 40 %) and a large amount of degradation products. Such preparations could not be used for assay purposes. It was early experienced that the ^{131}I had to be freshly prepared, thus it was normally used within 24 hours after the commercial preparation, and never later than 36 hours after the preparation.

For routine labeling lyophylised Roos GF 25 26 3 29 2, 39 2 48 and 53 were used. No significant differences could be shown between the preparations used for the assay. The yield of the labeling procedure was usually between 60—90 % giving a specific activity of 240—330 µc/µg, the preparation containing less than 1 atom of iodide per molecule HGH.

Since the problem of degradation damage is more pronounced for HGH than for other polypeptide hormones it is conceivable that the HGH molecule is more susceptible than other polypeptides. However HGH is more heterogeneous than other hormones (Hunter 1965 Berson and Yalow 1966, Trygstad 1967). The heterogeneity of the Roos preparation has already been demonstrated (Fig 7). Furthermore it has been shown that lyophylising Roos' preparations gives rise to further heterogeneity which may be due to polymerization (Hansson et al. 1966).

To determine whether differences in the storage conditions of Roos HGH alters the labeling product two different batches of HGH prepared by the same procedure were labeled. In one experiment a lyophylised and a frozen (in buffer 1) preparation of GF 57 were labeled simultaneously. In a second experiment GF 57 lyophylised and GF 60 never lyophylised nor frozen were labeled. The results are listed in Table II. The

TABLE II

Effect of storage of HGH on labeling

Preparation	Per cent yield of labeling	Sum of damaged in % of total protein (D)
GF 57 lyophylised	60	21.8
GF 57 frozen	60	18.1
GF 57 lyophylised	70	20.3
GF 60	[illegible]	12.3

yield of the labeling procedure seems to increase on lyophylising the preparations. On the other hand, the less manipulation with the hormone the fewer degradation products. This could indicate that the degradation damage in part is present already prior to the labeling and that this damaged fraction is more easily labeled by ^{131}I than is intact HGH. Further evidence for this will be published elsewhere (Westphal et al 1968)

Testing of antisera

Four different antisera were prepared simultaneously by the procedure described earlier They were tested in the following way Fifty µl of labeled HGH with a calculated concentration of 10 ng/ml was incubated with the antisera in final dilution of 1 10 000 1 100 000 1 250 000 1 500 000 1 1 000 000 and 1 1 500 000 the total volume being 500 µl The dilution giving a $\frac{B}{B+F}$ ratio of 50 % was chosen for mixing a standard curve with standard HGH amounts corresponding to 2 10 50 and 100 ng/ml. The standard curves showed almost identical slopes except for Ma 3 Fig 10 For immunoassay purposes and throughout this study antiserum Ma 1 in final dilution 1 500 000 was used.

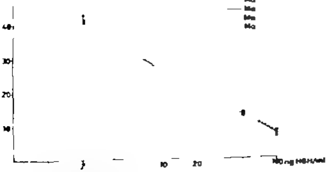

Fig 10 Standard curves determined for 4 different guinea pig antisera.

Effect of different concentrations of unlabeled HGH on the binding of labeled HGH (standard curve)

Fig 11 shows the mean and S D of ten consecutive standard curves plotted in a semilogarithmic diagram. Since the standard curve is very nearly linear between 2—100 ng/ml HGH it is very convenient to use this system

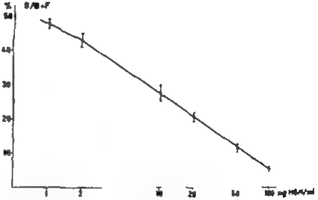

Fig 11 Mean and S.D of 10 consecutive standard curves plotted on a semilogarithmic system. The HGH standard was GF 29 2 Labeled hormone was GF 29 2 labeled on two different occasions and GF 39.2 labeled once Bars indicate S D

Effect of different amounts of labeled HGH

The $\frac{B}{B+F}$ ratio will increase if the amount of labeled HGH is decreased. (Fig 12) However since very small amounts of labeled hormone make the counting procedure inconvenient that amount of labeled HGH giving a B/B+F ratio of 50—55 % with the antiserum in final dilution 1 500 000 has been used for routine assays This has been checked on every freshly labeled hormone by incubating a standard curve with 4 different amounts of ^{131}I HGH as shown in Fig 13 For routine assays it gives a sufficient sensivity and a convenient number of counts.

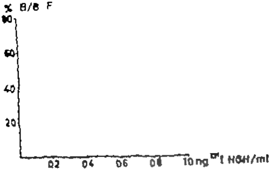

Fig. 12. B/B+F ratio without added standard HGH but various amounts of labeled hormone. Incubation time four days.

It is possible to increase the sensitivity of the assay by reducing the amount of labeled hormone, antiserum and consequently of standards. In a more diluted system however the equilibration time for the antigen-antibody reaction increases. If incubation time exceeds 7 days it is inconvenient. For special purposes however a more sensitive as well as a less sensitive system was prepared, Fig. 14.

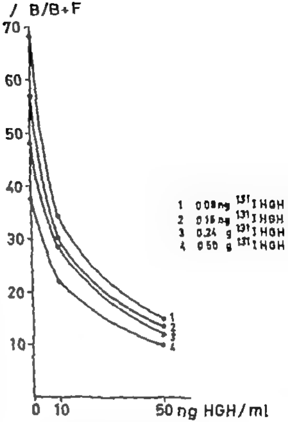

Fig. 13. Standard curves with various amounts of ^{131}I HGH. Dilutions as shown in the figure were made on every freshly labeled ^{131}I HGH preparation. The amounts giving B/B+F ratio of 30—35 % was used for the assay.

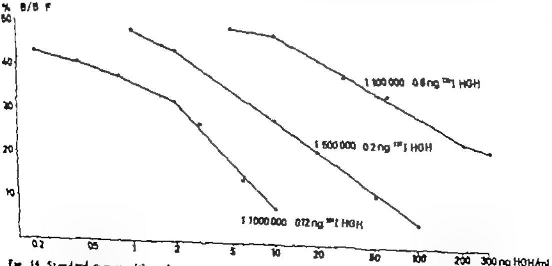

Fig. 14. Standard curves with various sensitivities of the assay. The concentrations of antiser were final dilutions 1:100 000, 1:100 000 and 1:1 000 000. The corresponding amounts of ^{131}I HGH were 0.8, 0.2 and 0.12 ng respectively. Incubation time was 3, 4 and 7 days respectively.

yield of the labeling procedure seems to increase on lyophylising the preparations. On the other hand the less manipulation with the hormone the fewer degradation products. This could indicate that the degradation damage in part is present already prior to the labeling and that this damaged fraction is more easily labeled by ^{131}I than is intact HGH. Further evidence for this will be published elsewhere (Westphal et al 1968)

Testing of antisera

Four different antisera were prepared simultaneously by the procedure described earlier They were tested in the following way Fifty µl of labeled HGH with a calculated concentration of 10 ng/ml was incubated with the antisera in final dilution of 1 10 000 1 100 000 1 250 000 1 500 000 1 1 000 000 and 1:1,500 000 the total volume being 500 µl The dilution giving a $\frac{B}{B+F}$ ratio of 50 % was chosen for mixing a standard curve with standard HGH amounts corresponding to 2 10 50 and 100 ng/ml The standard curves showed almost identical slopes except for Ma 3 Fig 10 For immunoassay purposes and throughout this study antiserum Ma 1 in final dilution 1 500 000 was used.

Effect of different amounts of labeled HGH

The $\frac{B}{B+F}$ ratio will increase if the amount of labeled HGH is decreased. (Fig. 12) However since very small amounts of labeled hormone make the counting procedure inconvenient that amount of labeled HGH giving a B/B+F ratio of 50—55 % with the antiserum in final dilution 1 500 000 has been used for routine assays This has been checked on every freshly labeled hormone by incubating a standard curve with 4 different amounts of ^{131}I HGH as shown in Fig 13 For routine assays it gives a sufficient sensivity and a convenient number of counts.

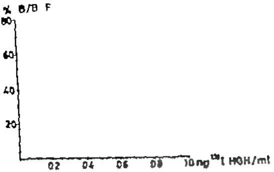

Fig 12. B/B+F ratio without added standard HGH but various amounts of labeled hormone. Incubation time four day

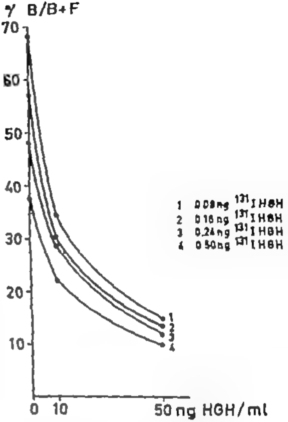

Fig. 13 Standard curves with various amounts of 131I HGH. Dilutions as shown in the figure were made on every freshly labeled 131I HGH preparation. The amounts giving B/B+F ratio of 50—55 % was used for the assay

It is possible to increase the sensitivity of the assay by reducing the amount of labeled hormone, antiserum and consequently of standards. In a more diluted system however the equilibration time for the antigen antibody reaction increases. If incubation time exceeds 7 days it is inconvenient. For special purposes however a more sensitive as well as a less sensitive system was prepared, Fig. 14

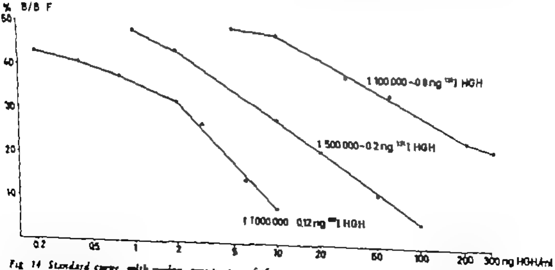

Fig. 14 Standard curves with various sensitivities of the assay. The concentration of antiserum were final dilutions 1:100 000, 1:500 000 and 1:1 000 000. The corresponding amounts of 131I HGH were 0.8, 0.2 and 0.12 ng respectively. Incubation time was 3, 4 and 7 days respectively

yield of the labeling procedure seems to increase on lyophylising the preparations. On the other hand, the less manipulation with the hormone the fewer degradation products. This could indicate that the degradation damage in part is present already prior to the labeling and that this damaged fraction is more easily labeled by ¹³¹I than is intact HGH. Further evidence for this will be published elsewhere (Westphal et al. 1968)

Testing of antisera

Four different antisera were prepared simultaneously by the procedure described earlier They were tested in the following way Fifty µl of labeled HGH with a calculated concentration of 10 ng/ml was incubated with the antisera in final dilution of 1 10 000 1 100 000 1 250 000 1 500 000 1 1 000 000 and 1:1,500 000 the total volume being 500 µl The dilution giving a $\frac{B}{B+F}$ ratio of 50 % was chosen for mixing a standard curve with standard HGH amounts corresponding to 2, 10 50 and 100 ng/ml The standard curves showed almost identical slopes except for Ma 3 Fig 10 For immunoassay purposes and throughout this study antiserum Ma 1 in final dilution 1 500 000 was used.

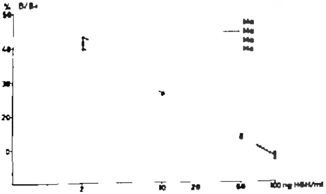

Fig 10 Standard curves determined for 4 different guinea pig antisera.

Effect of different concentrations of unlabeled HGH on the binding of labeled HGH (standard curve)

Fig. 11 shows the mean and S D of ten consecutive standard curves plotted in a semilogarithmic diagram Since the standard curve is very nearly linear between 2—100 ng/ml HGH it is very convenient to use this system.

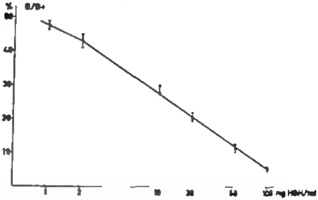

Fig 11 Mean and S.D of 10 consecutive standard curves plotted in a semilogarithmic system. The HGH standard was GF 29 2. Labeled hormone was GF 29 2 labeled on two different occasions and GF 39 2 labeled once Bars indicate S D

Effect of different amounts of labeled HGH

The $\frac{B}{B+F}$ ratio will increase if the amount of labeled HGH is decreased. (Fig 12) However since very small amounts of labeled hormone make the counting procedure inconvenient that amount of labeled HGH giving a B/B+F ratio of 50—55 % with the antiserum in final dilution 1 500 000 has been used for routine assays. This has been checked on every freshly labeled hormone by incubating a standard curve with 4 different amounts of ¹³¹I HGH as shown in Fig. 13 For routine assays it gives a sufficient sensivity and a convenient number of counts.

Effect of different concentrations of unlabeled HGH on the binding of labeled HGH (standard curve)

Fig 11 shows the mean and S.D of ten consecutive standard curves plotted in a semilogarithmic diagram. Since the standard curve is very nearly linear between 2—100 ng/ml HGH it is very convenient to use this system

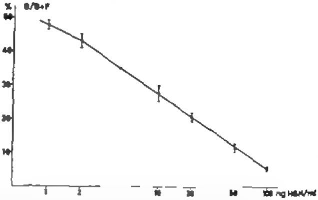

Fig 11 Mean and S.D of 10 consecutive standard curves plotted in a semilogarithmic system. The HGH standard was GF 29 2. Labeled hormone was GF 29 2 labeled on two different occasions and GF 39 2 labeled once Bars indicate S.D

Effect of different amounts of labeled HGH

The $\frac{B}{B+F}$ ratio will increase if the amount of labeled HGH is decreased. (Fig 12) However since very small amounts of labeled hormone make the counting procedure inconvenient that amount of labeled HGH giving a B/B+F ratio of 50—55 % with the antiserum in final dilution 1 500 000 has been used for routine assays. This has been checked on every freshly labeled hormone by incubating a standard curve with 4 different amounts of ^{131}I HGH as shown in Fig. 13 For routine assays it gives a sufficient sensitivity and a convenient number of counts.

Effect of degradation damage on standard curve

The precision of the radio-immunoassay decreases as the amount of damaged hormone increases (Berson et al. 1964) Since the amount of damage increases with prolonged storage or by storage of the labeled hormone at room temperature (Berson and Yalow 1966) four standard curves were run simultaneously with the same labeled hormone, the hormone being stored in different ways. The results are shown in Table III

Furthermore, three samples of the same HGH preparation (GF 39 2) were labeled on separate occasions and measured when one was one, another four and the third six weeks old. The preparations were kept at —20 C and had not been thawed prior to the experiment. The results are shown in Fig. 18

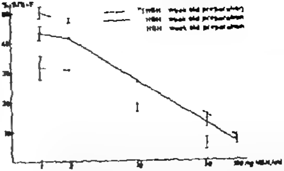

Fig. 18 Labeled HGH GF 39.2 from different labeling and with approximately the same amount of damage at time of preparation The preparations contained degradation damage of 17 %, 56.5 % and 49 % respectively at the time of the experiment. Bars indicate S D

TABLE III. *Effect of storage of labeled HGH*

Storage of preparation GF 39	Incubation damage	Per cent B/B+F ±S.D for various amounts of standard HGH 1 ng/ml	2 ng/ml	10 ng/ml	50 ng/ml
Frozen	19 %	49±2.2	44±2.1	28±1.8	12 ±0.8
+4°C 24 hours	22 %	48±2.0	43±2.7	27±1.5	11.9±0.9
20°C 6 hours	30 %	46±2.6	41±2.7	26±1.9	10.8±1.2
20°C 24 hours	46	38±3.9	36±3.7	23±2.7	8.7±2.1

Both experiments show that the slope of the standard curve is diminished when the damaged fraction increases and that will decrease the precision and consequently increase the S.D For assay purpose labeled hormone with a degradation fraction greater than 35 % has not been used. The labeling procedure was repeated every third or fourth week. The labeled hormone was kept at —20 C, it was thawed in a refrigerator at +4 C and was kept in an ice water bath during the mixing procedure. The incubation mixture was kept at +4 C until it was put on the paper strips for chromatography

Further effects of temperature on the assay

During early experiments with the assay duplicates of the standard curve and triplicates of plasma samples showed a significant difference between comparable samples. It was also noted that on those occasions the time of the buffer flow chromatography was prolonged and the variation between comparable strips pronounced. This effect increased during the day when the buffer used for the flow chromatography assumed room temperature. Since there was no sign of increase in degradation damage it was presumed that

Comparison between standard HGH and labeled HGH

On several occasions during the study the standard curve was compared with another obtained when labeled HGH was used as a standard. Fig 15 shows no significant differences in the immunological behaviour of the two standards

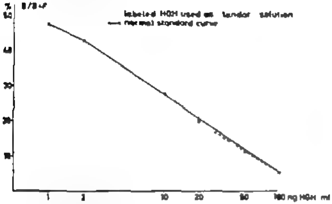

Fig 15 Standard curves with laboratory standard GF 29 2 and with labeled GF 39 2

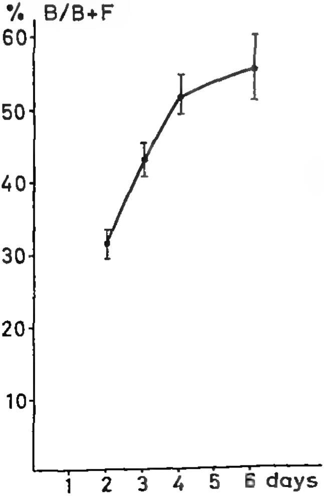

Fig 16. Effect of incubation time Bars indicate S.D

Effect of incubation time on binding of labeled HGH

For this experiment GF 29 2 was used for labeling. The amount of ^{131}I HGH was 0 15 ng/500 μl incubation mixture. Incubation periods of 2 3 4 and 6 days were studied and the results are given in Fig 16 No equilibrium in binding occurred during this period but the difference between four and six days was almost negligible. The S.D was greater in the six day incubated sample. The reason for this was an increase in the incubation damage. For the assay an incubation time of 4 days was routine

Effect of protein on standard curve

Differences in the effect of plasma on the assay have been published Hunter and Greenwood (1964) have stated that if plasma is diluted 1 5 or more no unspecific binding will occur while Cerasi et al (1966) show an unspecific binding in their double antibody assay For this purpose three different standard curves were mixed

1 Ordinary standard curve without protein during incubation.
2. Standard curve incubated with 50 μl of 7 % crystalline bovine serum albumin in barbital buffer 2.
3 Standard curve with 50 μl of heparinized bovine plasma.

As shown in Fig 17 no significant differences are noticable. Thus it is not necessary to incubate the standard curve with protein.

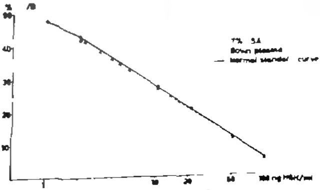

Fig 17 Effect of protein in incubation mixture on standard curves Incubation time four days

Effect of degradation damage on standard curve

The precision of the radio-immunoassay decreases as the amount of damaged hormone increases (Berson et al. 1964). Since the amount of damage increases with prolonged storage or by storage of the labeled hormone at room temperature (Berson and Yalow 1966) four standard curves were run simultaneously with the same labeled hormone, the hormone being stored in different ways. The results are shown in Table III.

Furthermore, three samples of the same HGH preparation (GF 39:2) were labeled on separate occasions and measured when one was one, another four and the third six weeks old. The preparations were kept at −20 C and had not been thawed prior to the experiment. The results are shown in Fig. 18.

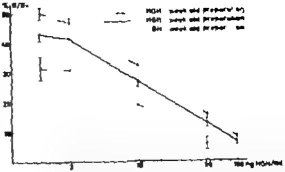

Fig. 18. Labeled HGH GF 39:2 from different labeling and with approximately the same amount of damage at time of preparation. The preparation contained degradation damage of 17 %, 36.5 % and 49 % respectively at the time of the experiment. Bars indicate S.D.

TABLE III. *Effect of storage of labeled HGH*

Storage of preparation CF 39	Incubation damage	Per cent B/B+F ±S.D. for various amounts of standard HGH 1 ng/ml	2 ng/ml	10 ng/ml	50 ng/ml
Frozen	19 %	49±2.2	44±2.1	28±1.8	12 ±0.8
+4°C 24 hours	22	48±2.0	43±2.7	27±1.5	11.9±0.9
20°C 6 hours	30 %	46±2.6	41±2.7	26±1.9	10.8±1.2
20°C 24 hours	46 %	38±3.9	36±3.7	23±2.7	8.7±2.1

Both experiments show that the slope of the standard curve is diminished when the damaged fraction increases and that will decrease the precision and consequently increase the S.D. For assay purpose labeled hormone with a degradation fraction greater than 35 % has not been used. The labeling procedure was repeated every third or fourth week. The labeled hormone was kept at −20 C, it was thawed in a refrigerator at +4 C and was kept in an ice water bath during the mixing procedure. The incubation mixture was kept at +4 C until it was put on the paper strips for chromatography.

Further effects of temperature on the assay

During early experiments with the assay duplicates of the standard curve and triplicates of plasma samples showed a significant difference between comparable samples. It was also noted that on those occasions the time of the buffer-flow chromatography was prolonged and the variation between comparable strips pronounced. This effect increased during the day when the buffer used for the flow chromatography assumed room temperature. Since there was no sign of increase in degradation damage it was presumed that

Comparison between standard HGH and labeled HGH

On several occasions during the study the standard curve was compared with another obtained when labeled HGH was used as a standard Fig 15 shows no significant differ ences in the immunological behaviour of the two standards.

Effect of incubation time on binding of labeled HGH

For this experiment GF 29 2 was used for labeling The amount of ^{131}I HGH was 0 15 ng/500 µl incubation mixture. Incubation periods of 2 3 4 and 6 days were studied and the results are given in Fig 16 No equilibrium in binding occurred during this period but the difference between four and six days was almost negligible. The S.D was greater in the six day incubated sample. The reason for this was an increase in the incubation damage. For the assay an incuba tion time of 4 days was routine.

Effect of protein on standard curve

Differences in the effect of plasma on the assay have been published. Hunter and Green wood (1964) have stated that if plasma is diluted 1 5 or more no unspecific binding will occur while Cerasi et al. (1966) show an unspecific binding in their double anti body assay For this purpose three different standard curves were mixed.

1 Ordinary standard curve without protein during incubation
2 Standard curve incubated with 50 µl of *7 % crystalline bovine serum albumin in barbital buffer 2*
3 Standard curve with 50 µl of heparinized bovine plasma.

As shown in Fig. 17 no significant differ ences are noticable. Thus it is not necessary to incubate the standard curve with protein.

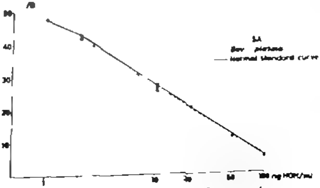

Fig 17 Effect f protein in incubation mixture on standard curves. Incubation time fou days

Application of the method to human plasma with special reference to neonatal plasma

All blood samples were collected in heparinized glass tubes (Vitrum, Stockholm, Sweden) volume 10 ml. If not otherwise stated the assay was performed as follows. A mixture of 0.2 ng ^{131}I HGH, guinea pig antisera to HGH, final dilution 1:500,000, standard HGH in various amounts for incubation of standard curve as described earlier or 50 µl plasma and buffer 3 to a final incubation volume of 500 µl was incubated for 4 days. The samples within one experiment are all run in the same series if not otherwise stated.

During the whole investigation two pooled samples were run in every series. One pooled sample was obtained prior to exchange transfusion from 3 children 4 days of age. The other pool was fasting blood from 3 healthy children 11 years of age. The estimated values were 33 $\pm$1.8 and 4.2 $\pm$0.8 ng/ml (50 determinations).

Effect of incubation time

The pooled samples were incubated 3, 4 and 6 days, respectively. The results are shown in Table V. Prolonged incubation seems to result in lower measurable concentration of HGH, and greater S.D., the latter due to increased degradation damage.

Effect of amounts of labeled HGH and antisera to HGH

The pooled samples were incubated 4 days with amounts of labeled HGH and antisera as shown in Fig. 14 and compared with corresponding standard curves. The results are shown in Table VI. Differences in the obtained results are not noticeable.

TABLE V. *Effect of incubation-time*

	HGH levels in ng/ml ± S.D. (5 estimations)	
Incubation-time	Neonatal plasma	Adolescent plasma
3 days	35 ± 4.2	3.8 ± 1.0
4 days	33 ± 4.2	3.0 ± 0.9
6 days	30 ± 5.9	2.5 ± 1.7

TABLE VI. *Effect of amounts of labeled HGH and antisera to HGH*

^{131}I HGH / Antisera		HGH levels in ng/ml ± S.D. (5 estimations)	
	Incubationstime	Neonatal plasma	Adolescent plasma
0.8 ng / 1:100,000	3 days	34 ± 4.1	<5 but >0
0.2 ng / 1:500,000	4 days	33 ± 3.8	3.1 ± 0.9
0.12 ng / 1:1,000,000	6 days	>10	3.1 ± 0.8

temperature had a direct influence on the flow chromatography An inadequate difference in temperature between buffer and surroundings presumably gave rise to an irregular rate of evaporation and buffer flow The temperature of the buffer was kept at +4°C with pieces of ice and the room temperature was not allowed to exceed 20°C. With these precautions the flow rate was rather constant and, the S D was diminished.

Cutting the paper strips

Initially the paper strips were monitored with a Geiger Müller tube with a small slit, the surface of the two peaks was calculated by planimetry This very time-consuming procedure was substituted by simply cutting the strips. They were then put in plastic tubes placed in an automatic sample changer and counted. The cutting was performed exactly halfway between the application line and the buffer flow indicator as seen in Fig 3 To test the accuracy of this cutting the two methods were compared by running 100 strips by both methods. The difference never exceeded ±2 % of the B/(B+F) ratio

Effects of other hormones on the assay

To check whether other hormones may influence the assay 50 µl of two concentrations of ACTH pituitary LH pituitary FSH chorionic gonadotrophin and insulin respectively were incubated 4 days with 0.2 ng ^{131}I HGH and HGH antiserum in final dilution 1 500,000 The results are shown in Table IV Only LH of pituitary origin and in high doses has any influence on the assay Probably the available LH preparation contained a small amount of HGH. The B/(B+F) ratio in samples with the other hormones tested did not exceed the B/(B+F) ratio of the standard tubes without any added standard HGH This would have been the case if the available antiserum contained antibodies against the actual hormones.

TABLE IV *Effect of some other hormones on the immunoassay of HGH*

Preparation	Amount ı ng	Apparent amou t of HGH ng/ml

0.12 ng / 1:1.000.000	6 days	>10	3.1 ± 0.8

Effect of storage on frozen plasma

The pooled plasma samples have been stored for a period of more than 2 years at —20°C The values obtained after 5 days 1 month 1 year and 2 years are shown in Table VII When the 5 days and 1 month samples were run the laboratory standard was GF 25 26 3 For the remaining samples the laboratory standard was GF 29 2. No difference in obtained HGH values was noted after 2 years storage at —20°

TABLE VII *Effect of storage of frozen plasma (—20°C)*

Time	HGH levels in ng/ml ± S D (5 estimations) Neonatal plasma	Adolescent plasma
5 days	34 ± 4.2	2.7 ± 0 9
1 month	31 ± 4 0	2.9 ± 1 0
1 year	32 ± 3 8	_4 ± 0.8
2 years	31 ± 4 1	3.2 ± 0 9

Effect of room temperature on whole blood and plasma

Freshly drawn blood samples from a 4 day old infant and from a healthy 11 year old girl were divided into two equal parts. One part was allowed to stand for various lengths of time at room temperature before it was spun down and the plasma separated and frozen The other part was immediately spun and the separated plasma allowed to stand for various lengths of time at room temperature before being frozen The results are shown in Table VIII No noticeable changes are seen in plasma samples if stored 6 hours at room temperature. In whole blood however a decrease in immunoreactive HGH is detectable within one hour in neonatal blood and within 2 hours in adolescent blood So the blood samples are immediately put in a refrigerator or in a beaker with ice and spun down and separated within one hour

TABLE VIII *Effect of room temperature on whole blood and plasma*

	HGH n g/ml plasma Mean ± S.D of 5 estimations			
	Neonatal		Ad lescent

Effect of freezing and thawing on plasma samples

Tubes containing 0.8 ml of pooled plasma were thawed and frozen various times. All samples were estimated in the same series. The results are shown in Table IX and show no effect of repeated thawing.

TABLE IX. *Effect of thawing and freezing on plasma levels of growth hormone*

Number of freezings	HGH in ng/ml plasma. Mean ±S.D of 5 estimations: Neonatal plasma	Adolescent plasma
1	19.5±2.1	3.2±0.9
2	20.5±1.1	3.2±0.8
5	21.8±1.6	3.7±0.5
10	21.7±1.9	3.4±0.7

Effect of hemolysis on plasma levels of immunoreactive growth hormone

Freshly drawn blood samples, one cord blood, one from a healthy 11 year old child were divided into 2 parts, the major portion was spun, the plasma separated and frozen. The minor part was immediately frozen to receive 100 % hemolysis without adding any substances. Twentyfour hours later the samples were thawed and different amounts of the hemolyzed blood were added to the plasma samples. The degree of hemolysis was measured by the method described by Martinek (1966). Results in Table X show that a fairly high amount of hemolysis is tolerated without interfering with the analysis. Very large amounts however will result in decreasing levels of HGH as well as an increase in S.D. Several explanations for the decrease of estimated immunoreactive HGH values are possible. One possibility is dilution of plasma with the intracellular fluid since the amount of HGH in the cells certainly is lower than in plasma. Furthermore the hemoglobin might act as a blocking agent on labeled HGH, which would simulate a *decrease of* available ^{131}I HGH, and with constant amount of antiserum the B/(B+F) ratio would increase, giving a *lower HGH* value. More probably however the hemoglobin interferes with the buffer-flow chromatography. Hemoglobin moves away from the application line as do other proteins. Probably it is able to carry away some of the antibody free intact ^{131}I HGH. This explanation also accounts for the fact that incubation damage as measured in control samples without antibody increases with increasing amount of hemolysis, giving an increase in S.D.

TABLE X. *Effect of hemolysis on HGH levels*

Per cent hemolysis	HGH in ng/ml plasma. Mean ±S.D of 5 estimations: Neonatal plasma	Adolescent plasma	Per cent hemolysis
0.005	75± 5.2	4.5±1.2	0.004
0.5	72± 4.0	3.7±0.9	0.4

2 years	31 ± 4 1	3.. ± 0.9

Effect of room temperature on whole blood and plasma

Freshly drawn blood samples from a 4 day old infant and from a healthy 11 year old girl were divided into two equal parts. One part was allowed to stand for various lengths of time at room temperature before it was spun down and the plasma separated and frozen The other part was immediately spun and the separated plasma allowed to stand for various lengths of time at room temperature before being frozen The results are shown in Table VIII No noticeable changes are seen in plasma samples if stored 6 hours at room temperature In whole blood however a decrease in immunoreactive HGH is detectable within one hour in neonatal blood and within 2 hours in adolescent blood. So the blood samples are immediately put in a refrigerator or in a beaker with ice and spun down and separated within one hour

TABLE VIII *Effect of room temperature on whole blood and plasma*

5	21.8±1.6	3.7±0.3
10	21.7±1.9	3.4±0.7

Effect of hemolysis on plasma levels of immunoreactive growth hormone

Freshly drawn blood samples, one cord blood, one from a healthy 11 year old child were divided into 2 parts, the major portion was spun, the plasma separated and frozen. The minor part was immediately frozen to receive 100 % hemolysis without adding any substances. Twentyfour hours later the samples were thawed and different amounts of the hemolyzed blood were added to the plasma samples. The degree of hemolysis was measured by the method described by Marinek (1966). Results in Table X show that a fairly high amount of hemolysis is tolerated without interfering with the analysis. Very large amounts however will *result in* decreasing levels of HGH as well as an increase in S.D. Several explanations for the decrease of estimated immunoreactive HGH values are possible. One possibility is dilution of plasma with the intracellular fluid since the amount of HGH in the cells certainly is lower than in plasma. Furthermore the hemoglobin might act as a blocking agent on labeled HGH, which would simulate a decrease of available ^{131}I HGH, and with constant amount of antiserum the B/(B+F) ratio would increase, giving a lower HGH value. More probably however the hemoglobin interferes with the buffer flow chromatography. Hemoglobin moves away *from* the application line as do other proteins. Probably it is able to carry away some of the antibody *free intact* ^{131}*I HGH.* This explanation also accounts for the fact that incubation damage as measured in control samples without antibody increases with increasing amount of hemolysis, giving an increase in S.D.

TABLE X. *Effect of hemolysis on HGH levels*

Per cent hemolysis	HGH in ng/ml plasma. Mean ±S.D. of 5 estimations Neonatal plasma	Adolescent plasma	Per cent hemolysis

Evaluation of the method

Recovery of exogenous HGH

The recovery of added HGH to neonatal and adult blood was studied The neonatal blood was drawn from a five day old infant of a diabetic mother the adult blood from a 25 year old student. The blood samples were divided in two equal parts one for recovery in blood, one for recovery in plasma. As for recovery in blood, the samples were rocked in room temperature 15 minutes after the addition of exogenous growth hormone and prior to the separation of the plasma. Plasma and blood samples were allowed to stand at room temperature for about 25 minutes including centrifugation time. The results are shown in Fig 19 and are summarized in Table XI

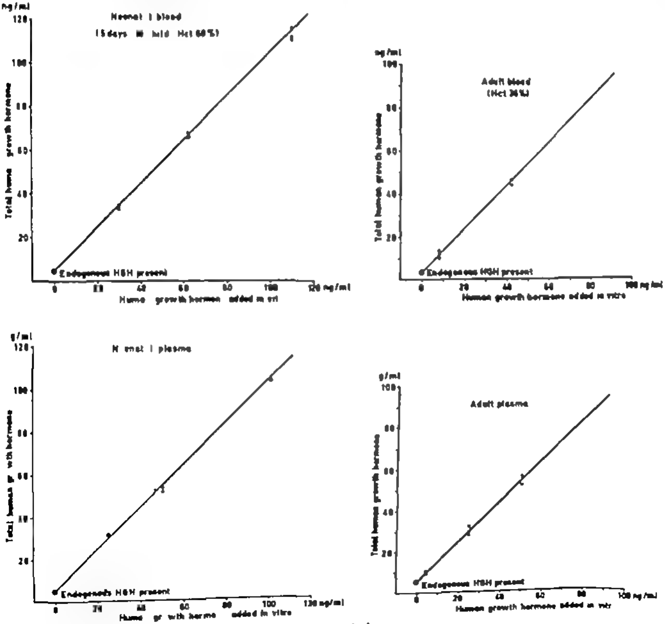

Fig 19 Recovery of exogenous HGH The lines indicate 100 % recovery

TABLE XI *Recovery of exogenous HGH*

Source	Per cent recovery (range)

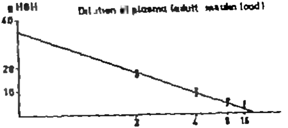
Adult plasma	92—110



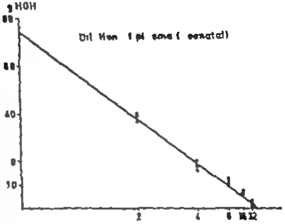


Fig 20 Dilution f plasma. Lines indicate teoretical dilution of simulate f undiluted plasma is true

Reproducibility

The results of the estimation of the two pooled samples (page 23) run on 20 different occasions over a period of 9 months were compared. The mean and S.D of the "between assay estimations were 33.38 ±1.7 ng/ml for the pooled neonatal plasma and 4.26 ±0.76 ng/ml for the adolescent plasma. This study was followed by a within comparison where 20 samples of both pooled plasmas were run in the same series. The within mean and S.D were 33.3 ±1.0 ng/ml and 4.2 ±0.58 ng/ml.

Accuracy of the assay

This has been studied in two ways.

1 Dilution of plasma. Plasma samples from an infant aged 6 hours and from a 25 year old student during insulin load were diluted serially No attempt was made to correct for arious amounts of protein during the incu bation of the samples. However for the buffer flow chromatography the total amount of protein was kept constant by addition of arious amounts of 7 /o bovine serum albu mi in 0 9 / saline. The results are shown in Fig 20 If accuracy is defined as the per cent of true level, the accuracy range is 94—120 /o for the adolescent plasma and 96—121 /o for neonatal plasma. If the results are subjected to a student s t test the variations do not significantly deviate from 100

– The 95 /o confidence limits with deter minations in triplicates were studied for plasma samples with respect to the variations in the standard curve. Such variations are not taken into account if the λ-value (S.D of points around the regression line divided by the slope of the regression line) is estimated which has been used by some authors (Hales and Randle 1963 Ceran et al. 1966) The 95 % confidence limits were about 20 % of the estimate which is in the same range as for other methods for immunoassay

Evaluation of the method

Recovery of exogenous HGH

The recovery of added HGH to neonatal and adult blood was studied. The neonatal blood was drawn from a five day old infant of a diabetic mother the adult blood from a 25 year old student. The blood samples were divided in two equal parts, one for recovery in blood, one for recovery in plasma. As for recovery in blood, the samples were rocked in room temperature 15 minutes after the addition of exogenous growth hormone and prior to the separation of the plasma. Plasma and blood samples were allowed to stand at room temperature for about 25 minutes including centrifugation time. The results are shown in Fig 19 and are summarized in Table XI

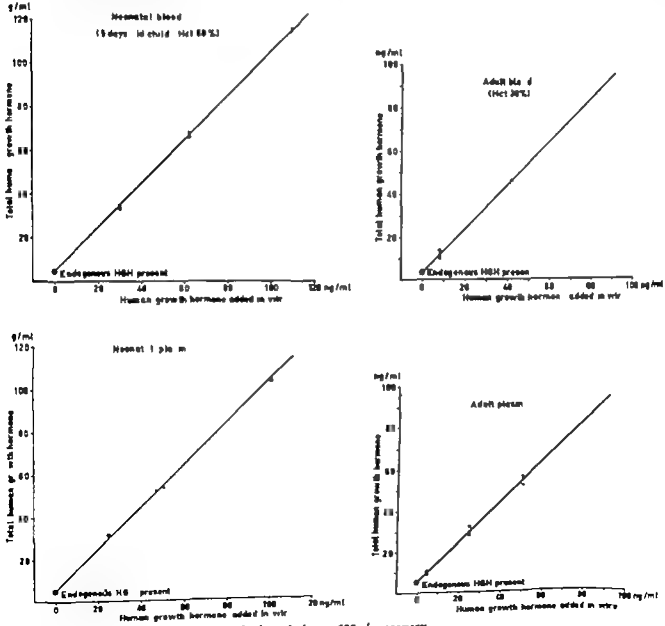

Fig 19 Recovery of exogenous HGH The lines indicat 100 / recovery

Clinical test of the method

The method has been tested on different groups of patients in order to compare the results obtained with those published by others.

Hypophysectomized patients

Two patients with certain total hypophysectomy for craniopharyngioma have been studied on several occasions after the operation. In all of totally 8 different plasma samples the obtained HGH level was <0.2 ng/ml when studied in the most sensitive assay used (page 19).

Acromegalic patients

The results are summarized in Table XII. The results agree with those published by Glick et al. (1963) and Hartog et al. 1964 a). Three acromegalic patients were studied during surgical hypophysectomy and the survival of endogenous HGH was observed. The results for two of the patients are shown in Fig. 21 and ... The half time for HGH for two of the patients was 24 and 28 minutes respectively. For the third patient surgical complications made the hypophysectomy very doubtful and that is proved by the half time of 150 minutes. All patients showed some persistent HGH secretion following hypophysectomy. This is consistent with previous studies (Glick et al 1964). The adherence of the capsule of the eosinophilic adenoma to surrounding blood vessels seems to make a total surgical extirpation impossible.

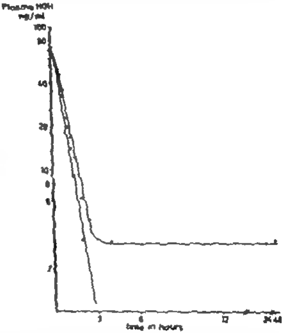

Fig. 21. Disappearance of growth hormone after hypophysectomy on ... acromegalic patient. —— indicate actual levels measured, o—o plasma levels after subtraction of residual constant concentration of 3 ng/ml. T ½ was calculated to be 24 minutes.

TABLE XII. *Fasting levels of HGH in acromegalic patients*

Source	No. of patients	Mean ± S.D. HGH ng/ml	Range HGH ng/ml
Acromegalic low activity	3	23 ± 12.1	12— 36
Acromegalic high activity	3	103 ± 26.3	71—138

Sensitivity

The sensitivity of the assay is expressed as the lowest HGH concentration giving a significant decrease in B/(B+F) ratio. The comparison is made between the B/(B+F) ratio in tubes where no standard HGH was added and the B/(B+F) ratio which corresponds to 0.5, 1 and 2 ng/ml. In 20 consecutive standard curves studied 14 showed differences between 0 and 1 ng/ml. All showed differences between 0 and 2 ng/ml ($p < 0.01$). So the sensitivity of the assay was on the level of 1 ng/ml. If the sensitivity was studied in the more sensitive system (Fig. 14) it was found to be on the level of 0.5 ng in all 10 standard curves studied.

Clinical test of the method

The method has been tested on different groups of patients in order to compare the results obtained with those published by others.

Hypophysectomized patients

Calculated $T_{1/2}$ is 150 minutes The hypophysectomy was complicated the patient showed clinical signs of acromegaly one month after operation. HGH levels at that time 76 ng/ml.

Cord blood and newborn infants

Samples of cord blood from 10 infants were studied The mean level was 40 2 ±10 6 (S D) This is in agreement with the results published by Cornblath et al (1965) and Laron et al. (1967) A special study of HGH levels in newborn infants is published in Part II

Children and adults

Fasting levels of normal children and adults are very low and not uncommon below 1 ng/ml Only a small series has been studied and the results are summarized in Table XIII They are in agreement with the results of others (Greenwood et al 1964)

It is of much greater interest to study the increase in HGH levels induced by hypoglycaemia first shown by Roth et al. (1963 a) This has been studied in a series of 16 normal children The results are discussed in detail in Part II The HGH response to insulin induced hypoglycaemia has been studied in 10 adults aged 22 to 47 years. The method was identical with that applied to children as described in detail in Part II The amount of insulin used to induce hypoglycaemia was 4 U per square meter body surface.

The results are summarized in Table XIV They are in good agreement with those published in the excellent survey of Greenwood et al. (1966)

Use of the labeled ^{131}I HGH for detection of antibodies

The labeled antigen is very useful for the purpose of detecting antibodies. If the labeled antigen when incubated with serum moves from its characteristic position in the free state to the position that in the separating system is occupied by bound antigen, then that serum will contain specific antibodies.

For growth hormone this is of special interest since it has been published that treatment with HGH will give rise to antibodies against HGH in some patients (Szêky et al. 1962 Roth et al. 1964)

Method for detection of HGH antibodies

The serum to be tested was serially diluted 1 1 1 2, 1:4 1 16 1:32, 1:64 etc. with buffer 3 From each dilution step 500 µl was incubated with 0 4 ng ^{131}I HGH for 24 hours at +4 C. The separation was performed with the buffer flow technique. The highest dilution that bound 50 % of the labeled hormone was taken as titre.

Results

All patients treated with HGH in our hands have been repeatedly tested for the presence of antibodies but none have been detected. In two serum samples with earlier proved antibodies (gift from Prof A Prader Zürich, Switzerland) the antibodies have been verified. These two test samples were always run as controls when tests for the presence of antibodies were performed. The only explanation for that is that our patients so far have not produced antibodies. This will be discussed further in Part II.

CHAPTER VIII

General discussion

In the radioimmunoassay it is assumed that the radioactively labeled and unlabeled hormones behave identically and that the circulating hormone is chemically and immunologically identical with the standard hormone preparation

The growth hormone used for this study has been prepared by the method of Roos et al (1963) The method of preparation is rather mild all procedures being performed in solutions of nearly neutral pH, and the method is favored by many investigators since the product seems less heterogeneous than most other preparations (Donato et al. 1966) This growth hormone however can be separated into several fractions as can other available preparations (Raben 1959 Ferguson and Wallace 1961 Gumbach and Kaplan 1962, Roos et al 1963 and Hunter 1965) In most instances such fractions have been shown to possess identical antigenic and/or biological activity (Gumbach and Kaplan 1962) In some, however quantitative differences have been shown (Ferguson and Wallace 1963 Hunter 1965) For the growth hormone used in this study it has been shown that one of four fractions, a minor portion of the total hormone preparation, has a decreased immunological activity but identical biological activity when compared with the other fractions Furthermore Trygstad (1967) has been able to separate a lipid mobilizing factor from the crude human pituitary extract and the subsequent separation of growth hormone yielded a more homogeneous somatotrophic hormone which gave a somatotrophic activity that was about 25 % higher on a weight basis than the HGH prepared according to the method of Roos et al (1963) That would agree with the suggestion by Levine and Luft (1964) that what we call HGH is a combination of two hormones one a growth promoting and the other a metabolic hormone. Available HGH would probably contain these two hormones in varying proportions.

Since radioimmunoassay is an inhibition technique and since plasma inhibits the reaction between labeled HGH and its antiserum, the plasma contains a protein which is immunologically identical with standard HGH obtained from human pituitaries if there is an exact parallel between equal dilutions of standard HGH and plasma. That is shown for this HGH preparation in Fig 20 and has been shown for other preparations (Hunter and Greenwood 1964) Until the growth hormone from plasma is quantitatively isolated and characterised it cannot be proved if its biological activity is similar to the immunological activity and if the immunological activity measured is representative for the metabolic and/or the somatotrophic action of HGH. Thus the HGH concentration in plasma obtained with radioimmunoassay should be called immunoreactive growth hormone The results published by different investigators however do not differ greatly and so far the method studied above is no exception. In the near future an international standard will be presented by W H.O This will make it easier to compare results obtained in different laboratories.

The preparation of labeled growth hormone and antiserum used for the method described above is similar to those used by other authors. The labeled hormone seems to be comparable with those used in other methods. The antiserum shows a sufficient avidity to the antigen giving a slope of the

standard curve (Fig. 5) of about 8 %. (The slope is defined as the decrease in per cent bound per doubling dose of standard (Hunter 1967 a). The steeper the slope of the standard curve, the greater the discrimination between two unknown samples and the greater the precision.) The slope is sufficient to give good precision but not so steep that the working range is restricted.

The problem of damaged HGH has been neglected in many radioimmunoassay systems. Berson et al. (1964) have stated that the sensitivity and precision of immunoassays is dependent upon the amount of damaged hormone present. For the present method it is shown that an increase in incubation damage will diminish the slope of the standard curve, and that will decrease the precision, with a corresponding increase in S.D. (Table III and Fig. 18).

Damaged HGH as shown by appearance of immunologically inert material may be caused by many factors. 1. Preparation of the hormone. Some studies indicate that HGH preparations prepared from the same starting material but handled in different ways during preparation show varying amounts of damage when labeled simultaneously under the same conditions (Westphal et al. 1968). 2. Manipulation with the hormone. As stated in the study above freezing and lyophylizing of the hormone increased the amount of damage. 3. Iodination of the hormone. a) Alteration of the hormone molecule due to substitution of iodine. If peptide hormones are heavily labeled there seem to be such alterations in the molecule that its immunological and chemical behaviour is altered. For HGH Hunter (1967 a) has shown that such alterations are not detectable if 7 or less atoms of iodine are substituted on the molecule. The labeling procedure used in this study will give less than 1 atom of iodine per molecule of protein. b) Radiation damage. This has been minimized in many ways. All reagents are kept as concentrated as possible, the total amount of ^{131}Iodide (2 mc) is small and the time of preparation very short. The separation on Sephadex is fast and after preparation the ^{131}I HGH is protected by the addition of protein and diluted. c) Chemical damage due to reagents used for labeling. Greenwood et al. (1963) could not prove any damage caused by chloramine-T when used in their labeling technique. Later Glover et al. (1967) stated that some damage of the protein may be due to the use of chloramine-T. The labeling method used in this investigation should be studied to see if a decrease in the amount of chloramine-T and consequently in meta-bisulfite will decrease the amount of damage without greater decrease in the yield of the labeling procedure resulting in decrease of the specific activity. d) Chemical damage due to noxious impurities in the radiochemical reagent. Such must occur at irregular intervals. As stated before, in periods the labeling has given a labeled product with a high amount of damage and a low yield of the labeling procedure. The results were identical for insulin when insulin and HGH were labeled simultaneously in this laboratory. The same experience has been claimed by Yalow and Berson (1967) and Hunter (1967 b). In 1963 Hunter was able to label HGH with specific activities up to 600 μc/μg using 4 mc ^{131}Iodide for 5 μg HGH without detectable damage. Since 1964 however damage frequently has occured when 2 mc were used for 5 μg HGH. It is an urgent desire of all concerned with labeling of proteins with these radioisotopes that the commercial producers of the isotope solve this problem. 4. Incubation with plasma. This problem has been discussed in detail for insulin by Yalow and Berson (1964). Incubation of ^{131}I HGH with diluted plasma (1:5 or more) will give only minor interference but the longer the incubation time the more pronounced is the problem. For this method it is shown in Fig. 16 that the increase of S.D. in the 6 days incubated samples is caused by increasing damage. The damage is caused by the protein and is due to alteration in the

General discussion

In the radioimmunoassay it is assumed that the radioactively labeled and unlabeled hormones behave identically and that the circulating hormone is chemically and immunologically identical with the standard hormone preparation

The growth hormone used for this study has been prepared by the method of Roos et al. (1963) The method of preparation is rather mild all procedures being performed in solutions of nearly neutral pH and the method is favored by many investigators since the product seems less heterogeneous than most other preparations (Donato et al 1966) This growth hormone, however can be separated into several fractions as can other available preparations (Raben 1959 Ferguson and Wallace 1961 Gumbach and Kaplan 1962, Roos et al. 1963 and Hunter 1965) In most instances such fractions have been shown to possess identical antigenic and/or biological activity (Gumbach and Kaplan 1962) In some however quantitative differences have been shown (Ferguson and Wallace 1963 Hunter 1965) For the growth hormone used in this study it has been shown that one of four fractions, a minor portion of the total hormone preparation has a decreased immunological activity but identical biological activity when compared with the other fractions. Furthermore Trygstad (1967) has been able to separate a lipid mobilizing factor from the crude human pituitary extract and the subsequent separation of growth hormone yielded a more homogeneous somatotrophic hormone which gave a somatotrophic activity that was about 25 % higher on a weight basis than the HGH prepared according to the method of Roos et al (1963) That would agree with the suggestion by Levine and Luft (1964) that what we call HGH is a combination of two hormones one a growth promoting and the other a metabolic hormone. Available HGH would probably contain these two hormones in varying proportions.

Since radioimmunoassay is an inhibition technique and since plasma inhibits the reaction between labeled HGH and its antiserum, the plasma contains a protein which is immunologically identical with standard HGH obtained from human pituitaries if there is an exact parallel between equal dilutions of standard HGH and plasma. That is shown for this HGH preparation in Fig 20 and has been shown for other preparations (Hunter and Greenwood 1964) Until the growth hormone from plasma is quantitatively isolated and characterised it cannot be proved if its biological activity is similar to the immunological activity and if the immunological activity measured is representative for the metabolic and/or the somatotrophic action of HGH. Thus the HGH concentration in plasma obtained with radioimmunoassay should be called immunoreactive growth hormone The results published by different investigators however do not differ greatly and so far the method studied above is no exception. In the near future an international standard will be presented by W H.O This will make it easier to compare results obtained in different laboratories

The preparation of labeled growth hormone and antiserum used for the method described above is similar to those used by other authors. The labeled hormone seems to be comparable with those used in other methods. The antiserum shows a sufficient avidity to the antigen giving a slope of the

standard curve (Fig. 5) of about 8 %. (The slope is defined as the decrease in per cent bound per doubling dose of standard (Hunter 1967 a) The steeper the slope of the standard curve, the greater the discrimination between two unknown samples and the greater the precision) The slope is sufficient to give good precision but not so steep that the working range is restricted.

The problem of damaged HGH has been neglected in many radioimmunoassay systems. Berson et al. (1964) have stated that the sensitivity and precision of immunoassays is dependent upon the amount of damaged hormone present. For the present method it is shown that an increase in incubation damage will diminish the slope of the standard curve, and that will decrease the precision, with a corresponding increase in S.D (Table III and Fig. 18)

Damaged HGH as shown by appearance of immunologically inert material may be caused by many factors. 1 Preparation of the hormone. Some studies indicate that HGH preparations prepared from the same starting material but handled in different ways during preparation show varying amounts of damage when labeled simultaneously under the same conditions (Westphal et al. 1968) 2. Manipulation with the hormone. As stated in the study above freezing and lyophylizing of the hormone increased the amount of damage. 3 Iodination of the hormone. a) Alteration of the hormone molecule due to substitution of iodine. If peptide hormones are heavily labeled there seem to be such alterations in the molecule that its immunological and chemical behaviour is altered. For HGH Hunter (1967 a) has shown that such alterations are not detectable if 7 or less atoms of iodine are substituted on the molecule. The labeling procedure used in this study will give less than 1 atom of iodine per molecule of protein. b) Radiation damage. This has been minimized in many ways. All reagents are kept as concentrated as possible, the total amount of ^{131}Iodide (2 mc) is small and the time of preparation very short. The separation on Sephadex is fast and after preparation the ^{131}I HGH is protected by the addition of protein and diluted. c) Chemical damage due to reagents used for labeling. Greenwood et al (1963) could not prove any damage caused by chloramine-T when used in their labeling technique. Later Glover et al. (1967) stated that some damage of the protein may be due to the use of chloramine T The labeling method used in this investigation should be studied to see if a decrease in the amount of chloramine-T and consequently in meta-bisulfite will decrease the amount of damage without greater decrease in the yield of the labeling procedure resulting in decrease of the specific activity d) Chemical damage due to noxious impurities in the radiochemical reagent. Such must occur at irregular intervals. As stated before, in periods the labeling has given a labeled product with a high amount of damage and a low yield of the labeling procedure. The results were identical for insulin when insulin and HGH were labeled simultaneously in this laboratory The same experience has been claimed by Yalow and Berson (1967) and Hunter (1967 b) In 1963 Hunter was able to label HGH with specific activities up to 600 µc/µg using 4 mc ^{131}Iodide for 5 µg HGH without detectable damage. Since 1964 however damage frequently has occured when 2 mc were used for 5 µg HGH. It is an urgent desire of all concerned with labeling of proteins with these radioisotopes that the commercial producers of the isotope solve this problem. 4 Incubation with plasma. This problem has been discussed in detail for insulin by Yalow and Berson (1964) Incubation of ^{131}I HGH with diluted plasma (1 5 or more) will give only minor interference but the longer the incubation time the more pronounced is the problem. For this method it is shown in Fig. 16 that the increase of S.D in the 6 days incubated samples is caused by increasing damage. The damage is caused by the protein and is due to alteration in the

General discussion

In the radioimmunoassay it is assumed that the radioactively labeled and unlabeled hormones behave identically and that the circulating hormone is chemically and immunologically identical with the standard hormone preparation

The growth hormone used for this study has been prepared by the method of Roos et al (1963) The method of preparation is rather mild all procedures being performed in solutions of nearly neutral pH, and the method is favored by many investigators since the product seems less heterogeneous than most other preparations (Donato et al. 1966) This growth hormone however can be separated into several fractions as can other available preparations (Raben 1959 Ferguson and Wallace 1961 Gumbach and Kaplan 1962, Roos et al 1963 and Hunter 1965) In most instances such fractions have been shown to possess identical antigenic and/or biological activity (Gumbach and Kaplan 1962) In some however quantitative differences have been shown (Ferguson and Wallace 1963 Hunter 1965) For the growth hormone used in this study it has been shown that one of four fractions a minor portion of the total hormone preparation has a decreased immunological activity but identical biological activity when compared with the other fractions. Furthermore Trygstad (1967) has been able to separate a lipid mobilizing factor from the crude human pituitary extract and the subsequent separation of growth hormone yielded a more homogeneous somatotrophic hormone which gave a somatotrophic activity that was about 25 % higher on a weight basis than the HGH prepared according to the method of Roos et al (1963) That would agree with the suggestion by Levine and Luft (1964) that what we call HGH is a combination of two hormones one a growth promoting and the other a metabolic hormone. Available HGH would probably contain these two hormones in varying proportions.

Since radioimmunoassay is an inhibition technique and since plasma inhibits the reaction between labeled HGH and its antiserum, the plasma contains a protein which is immunologically identical with standard HGH obtained from human pituitaries if there is an exact parallel between equal dilutions of standard HGH and plasma That is shown for this HGH preparation in Fig 20 and has been shown for other preparations (Hunter and Greenwood 1964) Until the growth hormone from plasma is quantitatively isolated and characterised it cannot be proved if its biological activity is similar to the immunological activity and if the immunological activity measured is representative for the metabolic and/or the somatotrophic action of HGH Thus the HGH concentration in plasma obtained with radioimmunoassay should be called immunoreactive growth hormone The results published by different investigators however do not differ greatly and so far the method studied above is no exception In the near future an international standard will be presented by W H.O This will make it easier to compare results obtained in different laboratories.

The preparation of labeled growth hormone and antiserum used for the method described above is similar to those used by other authors. The labeled hormone seems to be comparable with those used in other methods. The antiserum shows a sufficient avidity to the antigen giving a slope of the

standard curve (Fig. 5) of about 8 %. (The slope is defined as the decrease in per cent bound per doubling dose of standard (Hunter 1967 a) The steeper the slope of the standard curve, the greater the discrimination between two unknown samples and the greater the precision) The slope is sufficient to give good precision but not so steep that the working range is restricted.

The problem of damaged HGH has been neglected in many radioimmunoassay systems. Berson et al. (1964) have stated that the sensitivity and precision of immunoassays is dependent upon the amount of damaged hormone present. For the present method it is shown that an increase in incubation damage will diminish the slope of the standard curve, and that will decrease the precision, with a corresponding increase in S.D (Table III and Fig. 18)

Damaged HGH as shown by appearance of immunologically inert material may be caused by many factors. 1 Preparation of the hormone. Some studies indicate that HGH preparations prepared from the same starting material but handled in different ways during preparation show varying amounts of damage when labeled simultaneously under the same conditions (Westphal et al. 1968) 2. Manipulation with the hormone. As stated in the study above freezing and lyophylizing of the hormone increased the amount of damage. 3 Iodination of the hormone. a) Alteration of the hormone molecule due to substitution of iodine. If peptide hormones are heavily labeled there seem to be such alterations in the molecule that its immunological and chemical behaviour is altered. For HGH Hunter (1967 a) has shown that such alterations are not detectable if 7 or less atoms of iodine are substituted on the molecule. The labeling procedure used in this study will give less than 1 atom of iodine per molecule of protein. b) Radiation damage. This has been minimized in many ways. All reagents are kept as concentrated as possible, the total amount of ^{131}Iodide (mc) is small and the time of preparation very short. The separation on Sephadex is fast and after preparation the ^{131}I HGH is protected by the addition of protein and diluted. c) Chemical damage due to reagents used for labeling Greenwood et al. (1963) could not prove any damage caused by chloramine-T when used in their labeling technique. Later Glover et al. (1967) stated that some damage of the protein may be due to the use of chloramine-T The labeling method used in this investigation should be studied to see if a decrease in the amount of chloramine-T and consequently in meta-bisulfite will decrease the amount of damage without greater decrease in the yield of the labeling procedure resulting in decrease of the specific activity d) Chemical damage due to noxious impurities in the radiochemical reagent. Such must occur at irregular intervals. As stated before, in periods the labeling has given a labeled product with a high amount of damage and a low yield of the labeling procedure. The results were identical for insulin when insulin and HGH were labeled simultaneously in this laboratory The same experience has been claimed by Yalow and Berson (1967) and Hunter (1967 b) In 1963 Hunter was able to label HGH with specific activities up to 600 µc/µg using 4 mc ^{13} Iodide for 5 µg HGH without detectable damage. Since 1964 however damage frequently has occured when 2 mc were used for 5 µg HGH. It is an urgent desire of all concerned with labeling of proteins with these radioisotopes that the commercial producers of the isotope solve this problem. 4 Incubation with plasma. This problem has been discussed in detail for insulin by Yalow and Berson (1964) Incubation of ^{131}I HGH with diluted plasma (1 5 or more) will give only minor interference but the longer the incubation time the more pronounced is the problem. For this method it is shown in Fig. 16 that the increase of S.D in the 6 days incubated samples is caused by increasing damage The damage is caused by the protein and is due to alteration in the

physio-chemical and immunological properties of the labeled antigen The potency to cause damage seems to vary between different plasmas It is not prevented by the enzyme inhibitor difluorophosphate (Roth et al. 1964)

A factor not previously studied is the influence of hemolysis. As shown in Table X a moderate hemolysis can be tolerated while a pronounced hemolysis increases the incubation damage as it is tested in this system. To the author's knowledge no studies of the influence of hemolysis in other immunoassay systems have been published, so it is not possible to decide whether the effect of hemolysis is general or affects only the buffer flow chromatography separation used in this study

In the immunoassay described above, as well as in systems using electrophoresis or chromato-electrophoresis for separation of free and antibody bound hormones the damaged hormone will move with the antibody bound. If no correction for the damage is performed it will result in an underestimation. Thus for the standard curve as well as for each separate plasma estimated the approximate total amount of damage has been calculated as has been described earlier An upper limit of damage has been stated to be about 35 %.

Of other separating systems, the double-antibody technique is the most frequently used (Utiger & Parker 1962, Hartog et al. 1964 a, Schalch and Parker 1964 Cerasi et al. 1966 and Root et al. 1967) The interference of damage has not been discussed by the authors but should result in an overestimation since the immunologically inert damaged components are held in solution and read as free antigen. Some other factors however will influence the results in the opposite direction. Morgan et al (1964) showed a heat labile plasma inhibitor and that the method was influenced by the total amount of protein. Cerasi et al (1966) demonstrated that different HGH levels could be obtained when the amount of antiserum or the incubation time was changed. So the double antibody system causes several difficulties that make comparison between HGH levels obtained via different separation methods delicate

Storage of blood plasma samples The method used has been carefully tested especially for its application on neonatal plasma. However no differences between adolescent and neonatal plasma with regard to their behaviour in the assay have been proved with one exception When plasma or blood is kept at room temperature the HGH levels obtained successively decrease For adolescent plasma no alteration is noted within 24 hours, a fact which would permit transport of plasma without freezing or other precautions from a wide area surrounding the laboratory For neonatal plasma however a significant decrease can be noted after 14 hours. As for whole blood a significant decrease will be detectable after 4 hours for adolescent blood and within 2 hours for neonatal. The storage at room temperature is not followed by any increase in incubation damage. The reason for the decreased HGH levels measured may be due to changes in the immunological activity induced by enzymes in plasma and blood. Experiments with enzyme inhibitors however have not been performed. Consumption of growth hormone by the corpuscular element of the blood is another possibility However storage of plasma at —20°C will completely inhibit alterations in plasma since estimation of identical plasma over a time interval of two years gave identical results. Neither does freezing and thawing plasma give any changes in HGH levels obtained

CHAPTER IX

Final conclusions

The radioimmuno-chromatographic assay for HGH described seems suitable for the study of immunoreactive growth hormone in neonatal and adult plasma. The precision and sensitivity is comparable with other assays published, and the results obtained agree with those published by others. The problem of degradation damage has to be given special attention. However it is simple to make adequate corrections. The incubation time of four days permits a convenient laboratory routine and the capacity is sufficient for most purposes. The prepared labeled ^{131}I HGH and the flow chromatography separation are suitable for detection of antibody against HGH which is of importance for patients treated with HGH.

physio-chemical and immunological properties of the labeled antigen The potency to cause damage seems to vary between different plasmas. It is not prevented by the enzyme inhibitor difluorophosphate (Roth et al 1964)

PART II

Clinical Study of Human Growth Hormone in Children and Newborn Infants

PART II

Clinical Study of Human Growth Hormone in Children and Newborn Infants

PART II

Clinical Study of Human Growth Hormone in Children and Newborn Infants

CHAPTER X

Introduction

Since the radioimmunoassay for growth hormone became available in 1963 our knowledge of the regulation and function of growth hormone has rapidly increased. The first investigations (Hunter and Greenwood, 1964) showed rather low HGH levels in infants as well as in adults: the differences between patients were fairly large and normal control subjects showed resting levels of less than 1 ng/ml, which was the lowest sensitivity in routine assay for most methods. Roth et al. (1963 b) were the first to show that the HGH level was influenced by the actual blood glucose level. Hypoglycaemia was followed by a marked increase in plasma HGH if induced by insulin or by infusion of fructose or by 2-desoxy D glucose. Hyperglycaemia following glucose administration decreased growth hormone levels, but the subsequent decline of blood sugar concentration was followed by an increase in growth hormone. This made it possible to suggest tests for growth hormone release. A standardization of a test for the hypothalamo-pituitary axis and the secretion of growth hormone has been studied and proposed by Greenwood et al. (1966).

In the present study the HGH levels during the intravenous insulin tolerance test have been studied in four groups of patients.

1. Normal children.
2. Children with retardation of growth.
3. Children during long term treatment with corticosteroids.
4. Normal infants, infants of diabetic mothers and premature infants during the first week of life.

The growth hormone estimations have been performed by the method described in Part I. Thus the HGH levels obtained represent immunoreactive growth hormone.

In addition the results of treatment with HGH prepared by the method of Roos et al. (1963) will be presented.

Growth hormone release during insulin tolerance test in normal children

The first study of growth hormone levels in normal children was published by Hunter and Greenwood (1964). They showed that fasting levels in children were somewhat higher than those in adults but even in normal children fasting plasma samples may contain less than 1 ng/ml of HGH. Several authors (Roth et al. 1963 b Frantz and Rabkin 1964 and Greenwood et al., 1966) have published data about HGH response to insulin induced hypoglycaemia in adults but until recently only small series are published about similar studies in normal children (Greenwood 1964 Root et al. 1967 Parker et al. 1967 and Kaplan et al. 1968). The purpose of the present investigation was to study the HGH release due to insulin-induced hypoglycaemia in normal children.

Material and methods

Subjects. Sixteen children aged 5 to 15 years with normal growth and without any suspicion of endocrine disease were studied. They were all admitted to the hospital and were accustomed to the hospital routine.

Insulin tolerance test. Prior to the study the children fasted at least 12 hours. The test was started at about 8 o clock in the morning. A scalp vein needle was put in a peripheral vein and a slow saline infusion was started and maintained throughout the test to prevent clotting and make an immediate infusion of glucose possible. The total amount of saline infused did not exceed 100 ml. Before a blood sample was drawn the first ml containing blood and saline was discarded.

Crystalline insulin (Vitrum, Stockholm, Sweden) 4 U per square meter body surface was diluted to 1 ml in 0.9 % saline and injected I.V. followed by a wash of about 5 ml physiological saline. The insulin amount used in this study corresponds to about 1.5 U per kg body weight. Blood samples were withdrawn prior to, and 15 30 45 60 75 90 and 120 minutes after the injection of the insulin. The blood was put in glass tubes containing a small amount of heparin (Vitrum, Stockholm, Sweden). Blood for glucose estimation in duplicate was withdrawn immediately and precipitated. The glass tubes were placed in a beaker containing pieces of ice and when all samples were taken, the blood was spun down, the plasma withdrawn and frozen.

Blood glucose determinations were performed by an enzymatic method using 0.025 M NaOH and 10 % $ZnSO_4 - 7H_2O$ as precipitating agents (Hjelm and de Verdier 1963).

Growth hormone was estimated by the method described in Part I. All estimations were made in triplicate. Control samples for the estimation of incubation damage were taken from the first and the last tube of every load and the mean was used for correction of the bound fraction (page 13).

Results

The results are summarized in Table XV.

The blood glucose decrease was sufficient, the lowest levels were less than 50 % of fasting levels. In most of the children a slight sweating 25—30 minutes after the insulin gift was noted and few complained about moderate dizziness but it was not necessary to interrupt the test in any patient.

CHAPTER X

Introduction

Since the radioimmunoassay for growth hormone became available in 1963 our know ledge of the regulation and function of growth hormone has rapidly increased. The first in vestigations (Hunter and Greenwood, 1964) showed rather low HGH levels in infants as well as in adults, the differences between patients were fairly large and normal control subjects showed resting levels of less than 1 ng/ml which was the lowest sensitivity in routine assay for most methods. Roth et al. (1963 b) were the first to show that the HGH level was influenced by the actual blood glucose level Hypoglycaemia was followed by a marked increase in plasma HGH if in duced by insulin or by infusion of fructose or by 2-desoxy D glucose. Hyperglycaemia fol lowing glucose administration decreased growth hormone levels but the subsequent decline of blood sugar concentration was followed by an increase in growth hormone. This made it possible to suggest tests for growth hormone release. A standardization of a test for the hypothalamo-pituitary axis and the secretion of growth hormone has been studied and proposed by Greenwood et al (1966)

In the present study the HGH levels during the intravenous insulin tolerance test have been studied in four groups of patients

1 Normal children
2. Children with retardation of growth
3 Children during long term treatment with corticosteroids.
4 Normal infants, infants of diabetic mothers and premature infants during the first week of life

The growth hormone estimations have been performed by the method described in Part I Thus the HGH levels obtained represent immunoreactive growth hormone.

In addition the results of treatment with HGH prepared by the method of Roos et al (1963) will be presented.

16	15/6	m	4 59	5 31	24 24	32 38	29 51	22 59	10 71	8 63

The mean ± S D of the fasting *level of HGH* was 4 1 ± 2.4 ng/ml with a range between <1 (in two patients) to 8 ng/ml The peak level in most patients (10/16) was obtained 45 minutes after the insulin gift. Four patients reached their peak levels 30 minutes after the insulin injection and two after 60 minutes. The mean increment ± S D from the fasting level was 29 1 ± 11 5 ng/ml The *highest increments* occurred in the youngest children. The response fell with increasing age until a minimum was reached at the age of 11 years. Then the response increased again (Fig. 23)

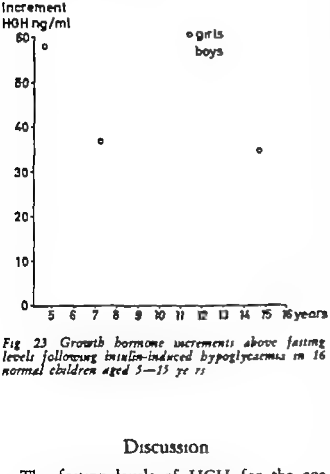

Fig 23 Growth hormone increments above fasting levels following insulin-induced hypoglycaemia in 16 normal children aged 5—15 ye rs

Discussion

The fasting levels of *HGH for the age* group studied corresponds well with those published by Greenwood et al (1964) and are slightly higher than those published by Root et al (1967) and Kaplan et al (1968)

The HGH *response* to hypoglycaemia in children is comparable with the response now *found in* adults (page 30) and in agreement with the results found in children by Greenwood (1964) using an electrophoretic technique. The results of Parker et al. (1967) are comparable with the present results since no differences were shown between children and adults. However their HGH levels are slightly lower than the present results and those of Greenwood et al (1966) This is probably explained by Parker s double antibody technique A lower response in children is reported by Root et al (1967) using a double antibody technique and by Kaplan et al (1968) using a chromato-electrophoretic technique. However no parallel studies of children and adults have been published by any of these authors. Several reasons for this difference between the studies are possible. There are variations in the immunoassay techniques as well as in HGH standards since no international standard is available at this time Another factor not studied in detail is the effect of different amounts of insulin used to induce hypoglycaemia. In the excellent survey of HGH response to insulin induced hypoglycaemia in adults by Greenwood et al. (1966) it was shown that the HGH response varied with the amount of insulin Most reliable results were obtained with an insulin amount of 0 15 U per kg body weight. In the present study the amount of insulin (4 U/m²) corresponds to about 0 15 U per kg body weight. In all other studies on children mentioned above however 0 1 U/kg was used. The suggestion by Kaplan et al. (1968) that *the reason for the depressed response* in HGH to hypoglycaemia in children is due to an altered sensitivity of the hypothalamus could be supported by the present study The greater amount of insulin used in this study induced a more powerful stimulus to the hypothalamus resulting in a pronounced HGH release.

In the present study the HGH response seems to change with the age of the patient. The highest response is obtained in the ranges 5—7 and 13—15 years, periods of most rapid growth. The same age variations have been found by Stimmler and Brown (1967) and

The mean ± S.D of the fasting *level of HGH* was 4 1 ± 2 4 ng/ml with a range between <1 (in two patients) to 8 ng/ml The peak level in most patients (10/16) was obtained *45 minutes after the insulin gift.* Four patients reached their peak levels 30 minutes after the insulin injection and two after 60 minutes The mean increment ± S.D from the fasting level was 29 1 ± 11.5 ng/ml The highest increments occurred in the youngest children The response fell with increasing age until a minimum was reached at the age of 11 years. Then the response increased again (Fig. 23)

Fig 23 Growth hormone increments above fasting levels following insulin-induced hypoglycaemia in 16 normal children aged 5—15 years

Discussion

The fasting levels of HGH for the age group studied corresponds well with those published by Greenwood et al (1964) and are slightly higher than those published by Root et al. (1967) and Kaplan et al (1968)

The HGH response to hypoglycaemia in children is comparable with the response now found in adults (page 30) and in agreement with the results found in children by Greenwood (1964) using an electrophoretic technique. The results of Parker et al. (1967) are comparable with the present results since no differences were shown between children and adults However their HGH levels are slightly lower than the present results and those of Greenwood et al. (1966) This is probably explained by Parker's double antibody technique. A lower response in children is reported by Root et al. (1967) using a double antibody technique and by Kaplan et al. (1968) using a chromato-electrophoretic technique However no parallel studies of children and adults have been published by any of these authors. Several reasons for this difference between the studies are possible. There are variations in the immunoassay techniques as well as in HGH standards since no international standard is available at this time Another factor not studied in detail is the effect of different amounts of insulin used to induce hypoglycaemia. In the excellent survey of HGH response to insulin induced hypoglycaemia in adults by Greenwood et al. (1966) it was shown that the HGH response varied with the amount of insulin Most reliable results were obtained with an insulin amount of 0 15 U per kg body weight. In the present study the amount of insulin (4 U/m²) corresponds to about 0 15 U per kg body weight In all other studies on children mentioned above, however 0 1 U/kg was used. The suggestion by Kaplan et al. (1968) that the reason for the depressed response in HGH to hypoglycaemia in children is due to an altered sensitivity of the hypothalamus could be supported by the present study The greater amount of insulin used in this study induced a more powerful stimulus to the hypothalamus resulting in a pronounced HGH release.

In the present study the HGH response seems to change with the age of the patient. The highest response is obtained in the ranges 5—7 and 13—15 years, periods of most rapid growth The same age variations have been found by Stimmler and Brown (1967) and

Growth hormone release during insulin tolerance test on children of short stature

The diagnosis of hypopituitary dwarfism in children has been a matter of great difficulty. Stunted growth is the obligate symptom but since this is a common occurrence in childhood the differential diagnoses have made necessary a number of time demanding investigations which too often have not yielded a precise answer. Previously it was believed that the growth in hypopituitarism in children was not impaired during the first two years of life. However in the review of Brasel et al. (1965) it was stated that in nearly half of the children with idiopathic hypopituitarism the growth was retarded at the age of two years and 35 % showed growth retardation already at the age of one year. This is in agreement with the results of Aarskog (1963). Absence of gross structural abnormalities such as craniopharyngioma and of deficiency in other trophic hormones measurable by functional defects in the target glands, make the diagnosis idiopathic hypopituitarism very difficult. An increased insulin sensitivity has been used to confirm the diagnosis hypopituitary dwarfism and the blood glucose levels during insulin glucose tolerance test (Trygstad 1965) were the main diagnostic evidence for Seip and Trygstad (1966) to find patients suitable for HGH treatment.

Measurement of growth hormone levels in children of short stature became possible in 1963 and studies on patients with stunted growth have been published by Root et al. (1967) Parker et al. (1967) Frohman et al. (1967) Stimmler and Brown (1967) and Kaplan et al. (1968). In the present investigation children with suspected hypopituitarism primordial dwarfism, constitutional growth retardation, Turner's syndrome and chondrodystrophy have been studied. The aim of the investigation was to study the HGH response to insulin-induced hypoglycaemia on children of short stature and to see whether a subnormal response as defined in Chapter XI was correlated to hypopituitary dwarfism.

Material and methods

Subjects: Growth hormone response to insulin-induced hypoglycaemia has been studied in 31 children of short stature. Furthermore a boy of normal height with a craniopharyngioma was studied prior to and following hypophysectomy. The patients have been divided into four groups: 1) hypopituitary dwarfs, 2) premordial dwarfism and constitutional growth delay, 3) Turner's syndrome and 4) chondrodystrophic dwarfs. The classification was based on criteria stated by Wilkins (1965). Furthermore successful treatment with HGH (chapter XIII) was required for the diagnosis of hypopituitarism. However treatment could not be tried in all children of short stature owing to the limited supply of HGH. Patients with subnormal or borderline HGH response to insulin induced hypoglycaemia as defined in chapter XI have been treated for at least six months. Patients with no clinical signs of hypopituitarism and with normal HGH response have not been treated. Using this basis for classification the groups are as follows.

Hypopituitarism: nine children. In five children with idiopathic hypopituitarism, deficiencies in multiple trophic hormones were found, in two only a single growth hormone deficiency has been shown so far.

Kaplan et al. (1968) in their studies on children of short stature.

The range in HGH response is very wide for all studies presented. This makes it difficult to establish the lowest response that can be accepted as normal when the method is used for the comparison between normal subjects and those with various diseases, especially growth retardation. For the present study a growth hormone increase above 10 ng/ml has been adopted as lower limit. This is in agreement with the studies of Greenwood et al. (1966) and Frohman et al. (1967) and comparable with the results of Kaplan et al. (1968). Borderline response occurs in some cases and further provocation tests may be necessary to prove the right diagnosis, as will be discussed later (Chapter XII).

Summary

The growth hormone response to insulin induced hypoglycaemia has been studied in 16 children aged 5 to 15 years. The mean $\pm$ S.D. HGH increase during hypoglycaemia was 29.1 ± 11.5 ng/ml which is of approximately the same size as earlier found in adults. The response varied with age of the children, the response being most pronounced in the age groups where growth is accelerated.

The results are in agreement with those published by Greenwood (1964) and Parker et al. (1967) but not in agreement with those published by Root et al. (1967) and Kaplan et al. (1968). Differences in HGH standard, immunoassay techniques and amount of insulin used to induce hypoglycaemia are probable explanations for the differences. It is concluded from the results of the present study that a normal response to insulin induced hypoglycaemia can be defined as an HGH increase of 10 ng/ml above fasting levels.

Growth hormone release during insulin tolerance test on children of short stature

The diagnosis of hypopituitary dwarfism in children has been a matter of great difficulty. Stunted growth is the obligate symptom but since this is a common occurrence in childhood the differential diagnoses have made necessary a number of time demanding investigations which too often have not yielded a precise answer. Previously it was believed that the growth in hypopituitarism in children was not impaired during the first two years of life. However in the review of Brasel et al. (1965) it was stated that in nearly half of the children with idiopathic hypopituitarism the growth was retarded at the age of two years and 35 % showed growth retardation already at the age of one year. This is in agreement with the results of Aarskog (1963). Absence of gross structural abnormalities such as craniopharyngioma and of deficiency in other trophic hormones measurable by functional defects in the target glands, make the diagnosis idiopathic hypopituitarism very difficult. An increased insulin sensitivity has been used to confirm the diagnosis hypopituitary dwarfism and the blood glucose levels during insulin glucose tolerance test (Trygstad 1965) were the main diagnostic evidence for Seip and Trygstad (1966) to find patients suitable for HGH treatment.

Measurement of growth hormone levels in children of short stature became possible in 1963 and studies on patients with stunted growth have been published by Root et al. (1967), Parker et al. (1967), Frohman et al. (1967), Stimmler and Brown (1967) and Kaplan et al. (1968). In the present investigation children with suspected hypopituitarism, premordial dwarfism, constitutional growth retardation, Turner's syndrome and chondrodystrophy have been studied. The aim of the investigation was to study the HGH response to insulin-induced hypoglycaemia on children of short stature, and to see whether a subnormal response as defined in Chapter XI was correlated to hypopituitary dwarfism.

Material and methods

Subjects. Growth hormone response to insulin-induced hypoglycaemia has been studied in 31 children of short stature. Furthermore a boy of normal height with a craniopharyngioma was studied prior to and following hypophysectomy. The patients have been divided into four groups: 1) hypopituitary dwarfs, 2) premordial dwarfism and constitutional growth delay, 3) Turner's syndrome and 4) chondrodystrophic dwarfs. The classification was based on criteria stated by Wilkins (1965). Furthermore successful treatment with HGH (chapter XIII) was required for the diagnosis of hypopituitarism. However treatment could not be tried in all children of short stature owing to the limited supply of HGH. Patients with subnormal or borderline HGH response to insulin-induced hypoglycaemia as defined in chapter XI have been treated for at least six months. Patients with no clinical signs of hypopituitarism and with normal HGH response have not been treated. Using this basis for classification the groups are as follows.

Hypopituitarism: nine children. In five children with idiopathic hypopituitarism, deficiencies in multiple trophic hormones were found, in two only a single growth hormone deficiency has been shown so far

In two patients the hypopituitarism was due to craniopharyngioma, one of these was of normal height. HGH deficiency and diabetes insipidus, but without any tumour demonstrable by repeated pneumoencephalograms, were present in one child.

Clinical data pertaining to the patients are summarized in Table XVI

Patients with constitutional growth delay and with premordial dwarfism No distinction is made between these groups since each group probably represents a heterogeneous mixture with respect to etiology Four of the fifteen patients showing borderline HGH response to insulin induced hypoglycaemia and with clinical signs that made hypopituitary origin of the growth retardation probable have been treated for six months with HGH without success and are thus included in this group Clinical data pertaining to these patients are summarized in Table XVII

Five children with Turner s syndrome All five children showed clinical stigmata of Turner s syndrome.

Two patients with chondrodystrophy They showed characteristic clinical and radiological stigmata Clinical data in Table XVIII

Insulin tolerance test The test, including measurements of blood glucose and HGH was permormed as described earlier (page 39)

The thyrotrophic function was studied indirectly by measurement of PBI* using a Technicon Auto Analyzer (1964) The normal range in the laboratory is 3 5—7 5 μg/100 ml

ACTH function was studied indirectly by measurement of the output of 17-OH corticosteroids in urine on oral administration of 3 g metyrapone divided in 6 doses during 24 hours.

The gonadotrophic function was studied in 28 patients. The excretion of urinary FSH** was estimated after extraction according to Johnsen (1958) by the method of Steelman and Pohley (1953) modified using 40 U of HCG per animal one injection per day for three days. The standard preparation used was the 2nd IRP for FSH. Levels less than 4 U/24 hours were undetectable. The LH*** excretion in urine has been estimated by the hemagglutination inhibition technique (Wide et al 1961) in a minority of the patients and by the radioimmunosorbent technique (Wide and Porath 1966) in most patients. The standard used was 2nd IRP for LH. Levels less than 4 U/24 hours indicate insignificant levels

*The karyotype***** has been studied in all patients in cultures of leucocytes from peripheral blood.

Measurements of standing height. In all children height measurements were performed in the morning the first three days in the hospital the mean was accepted as the true height.

Height age was calculated from the diagram of Karlberg Iggbom (1959)

Bone age estimations were performed by the method of Eklöf and Ringertz (1967)

Results

The increments of HGH to insulin induced hypoglycaemia are compared with the increments for normal children in Fig 24

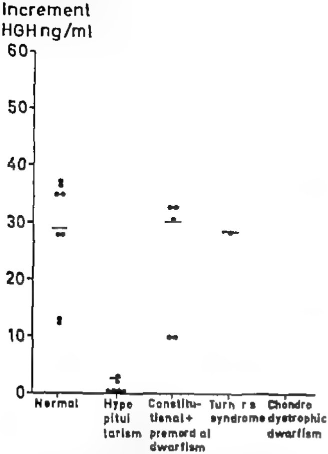

Fig 24 Growth hormone increments from fasting levels following insulin-ind ced hypoglycaemia in 16 n rm l children and 31 children with stunted growth The hori ont l lin s indic t the mean increment for the group

Hypopituitarism Blood glucose and HGH levels are shown in Table XIX. Five of the patients showed a pathological insulin load with low blood glucose levels and persistent hypoglycaemia. In one case (no 2) the insulin load had to be interrupted by glucose infusion 28 minutes after the insulin gift. Two patients had a history of spontaneous hypoglycaemia.

Base levels of HGH were less than 1 ng/ml in six of the patients. Four patients showed no measurable increase in HGH levels during the insulin load and four patients showed subnormal response. Furthermore one patient with stunted growth due to craniopharyngioma showed a subnormal increase and one patient with normal growth in spite of craniopharyngioma showed normal HGH response prior to the operation but failed to increase in HGH after the hypophysectomy

The results of other laboratory investigations are summarized in Table XX.

PBI was decreased and the response to metyrapone was poor in 5 of the 7 patients with idiopathic hypopituitarism. The patients with craniopharyngioma had normal response. Only one patient (one with craniopharyngioma) showed any gonadotrophic activity All patients had a normal karyotype. Height age and bone age were markedly retarded in all patients with HGH deficiency at the time of the study In three of the patients it was possible to detect growth retardation at the age of two years. As the years passed the gap between the child s growth and normal growth increased for all patients.

Constitutional and premordial dwarfism The laboratory investigations are summarized in Table XXI The blood glucose was decreased to less than 50 % of the fasting level in all children with a mean of 41 % of fasting level and a range of 28—47 %. Two patients showed an increased insulin sensitivity with prolonged hypoglycaemia.

Fasting levels of HGH varied between 1 and 8 ng/ml and the maximal increment between 7 and 62 ng/ml with a mean ± S D of 30 9 ± 15 9 ng/ml. This is in agreement with the results obtained with normal children. Two patients showed insufficient HGH increase, defined earlier as an increment less than 10 ng/ml (page 42) and these two patients also showed an increased insulin sensitivity One of them (case 22) had a history of hypoglycaemic weakness. Two patients showed borderline HGH response.

PBI was normal in all children. A poor response to metyrapone was noticed in three patients of which two were the patients with subnormal HGH response and one showed a borderline HGH response. The gonadotro-

10 prior to operation of craniopharyngioma.
10 b 3 months after operation
After the injection of glucose.
**5 hours after insulin injection the blood glucose was 36 mg/100 ml in spite of two meals in the meantime

phins were moderately elevated in 5 of 7 patients aged 11 years or more. Of the two patients without gonadotrophic activity one showed a subnormal HGH response, and the other a borderline response.

The karyotype was normal in all children. Height age was retarded with a minimum of two years. Bone age was retarded in ten of the patients.

In all patients with Turner's syndrome (laboratory results in Table XXII) the blood glucose fell to less than 50 % of fasting level (mean 40 %, range 31—45 %)

Fasting levels of HGH varied between 3 and 8 ng/ml and the response to hypoglycaemia was of the same order as that for normal children. The mean ± S.D was 28.4 ± 5.7 ng/ml and the range 22—37 ng/ml.

The PBI and the response to metyrapone was normal. The gonadotrophins were high in patients aged 13 years or more. In four patients the karyotype was 44 + XO and in

Results

The increments of HGH to insulin induced hypoglycaemia are compared with the increments for normal children in Fig 24

31	—	—	—	—	—	3.0	42
32	—	—	—	—	—	6.0	29

one patient the karyotype was 44 + XXL with iso-chromosome for the long arm of the X chromosome The bone age was moderately delayed in the patients aged 17 and 21 years.

The two patients with chondodystrophic dwarfism (laboratory results in Table XXII) showed a normal blood glucose decrease The fasting levels of HGH were 3 and 6 ng/ml respectively and the increments 42 and 29 ng/ml respectively The karyotype was normal as was the bone age.

Discussion

Hypopituitarism Five of the patients showed an *increased sensitivity to insulin* These five children had a poor response to metyrapone so a combination of HGH and ACTH deficiency seems to increase the risks for serious hypoglycaemia. This is in agreement with the results of Kaplan et al. (1968) The blood glucose has not been studied in the period between 20 and 30 minutes after insulin injection which makes a comparison with the study of Trygstad (1965) impossible.

All patients showed low HGH response. This is in agreement with all earlier studies. Five patients with idiopathic hypopituitarism showed a deficiency in corticotrophic as well as in thyrotrophic action

The retardation of bone age was most pronounced in this group of patients when compared to other groups of stunted growth as stated earlier by Clayton et al. (1967)

Constitutional retarded growth and premordial dwarfism The reason for the increased insulin sensitivity in two cases (nos. 22 and 25) combined with spontaneous hypoglycaemia in one of them is not clearly understood Both of them showed a subnormal HGH response, a poor response to metyrapone and a marked retardation of both bone age and height age This made the diagnosis hypopituitary dwarfism probable and the patients were treated for six months with 2 mg HGH twice a week During this period however no increase in growth occurred Two other patients showed border line response to HGH (cases 17 and 23) one of them showing a poor metyrapone response (23) and both having markedly retarded bone age and height age. Even in these patients treatment with HGH had been tried without any acceleration in growth The discovery of patients with stunted growth of non pituitary origin but poor response to insulin induced hypoglycaemia is in agreement with the results of Kaplan et al. (1965) Parker et al (1967) Stimmler and Brown (1967) and Kaplan et al. (1968)

PBI was normal in all patients and the response to metyrapone was normal in all except those discussed above. Gonadotrophins were present in all except two patients aged 13 years or more. Absence of gonadotrophins was noted in cases number 22 and 23 which increased the suspicion of pituitary origin of growth retardation in these patients. To the author's knowledge no studies of gonadotrophins in these groups of patients have been published.

The retardation of bone age varies from patient to patient since the group is rather heterogeneous However the bone age is more retarded in those patients which may be classified as premordial dwarfs. The growth for the constitutional dwarfs seemed to follow normal growth the gap between actual height and normal height was almost constant during the years the patients have been followed. As for most of the premordial dwarfs the gap between actual height and normal height seemed to increase but not to the same extent as in hypopituitarism. This was also found by Clayton et al. (1967)

Turner's syndrome and chondrodystrophic dwarfism The results for the patients with Turner's syndrome are in agreement with the results of Root et el. (1967) and Kaplan et al. (1968) As for the two patients with chondrodystrophy the growth hormone fasting levels and the release was normal. This is in agreement with results found by Beck (1965)

The insulin susceptibility has long been used as a diagnostic test. However in this study as well as in others the insulin sensitivity seems to be marked only in patients where an ACTH deficiency is also present. Furthermore insulin sensitivity may be present without any hyposomatotrophinism.

The tests of other pituitary trophic hormones are valuable in some cases but they are all time demanding and do not prove HGH deficiency.

At this time no method for the study of HGH deficiency seems to be absolute reliable. There are patients on whom available diagnostic tests fail. In such cases a test period with HGH treatment seems to be the only possible way to make a clear diagnosis. It is necessary that this treatment is long enough since short treatment may be misleading due to seasonal changes in growth or due to transient acceleration of growth.

Summary

The HGH response to insulin induced hypoglycaemia has been studied in 31 children with short stature. Ten patients have been classified as hypopituitary dwarfs, and all these patients showed an HGH increment of less than 10 ng/ml from fasting levels. In six of these there were signs of deficiency of other pituitary hormones and two had a craniopharyngioma. In fifteen children the diagnosis was premordial dwarfism or constitutional delay in growth. Two patients in this group showed a subnormal HGH response to insulin-induced hypoglycaemia. In five patients with Turner's syndrome and in two patients with chondrodystrophy the HGH response was normal when compared to a control group. Other parameters compared were the blood glucose levels during the insulin-induced hypoglycaemia, PBI, excretion of 17-OH corticosteroids after metyrapone, urinary gonadotrophins and the bone age. The difficulties in the interpretation of different tests are discussed and some other possible tests for the study of HGH release have been described. On the basis of this study measurements of HGH levels during insulin-induced hypoglycaemia is a useful aid in the diagnosis of hypopituitarism. When borderline results are found further tests or short term therapy with HGH is necessary.

The response to insulin induced hypoglycaemia was less than normal in all patients with dwarfism of pituitary origin However subnormal response was also shown in two patients where HGH deficiency was not the reason for the growth retardation. One factor that influences the HGH response seems to be fasting HGH concentration Frohman et al (1967) and Kaplan et al (1968) have shown that subnormal response to hypoglycaemia is more common in patients where the fasting levels are high. This is not seen in the present study but its absence is probably coincidental and the two patients with subnormal response in this study had low fasting levels of HGH. Hypothyroidism was found to decrease HGH response in three patients studied by Root et al (1967) As shown by Hartog et al (1964 b) and in a study by the author (chapter XIV) glucocorticoid excess also depresses HGH response However there were no signs of hypothyreosis or increased corticosteroid secretion in the two patients with subnormal response

The response in HGH release to insulin induced hypoglycaemia is a very useful test in the diagnosis of hyposomatotrophinism in most cases. The risk of severe hypoglycaemia can be neglected if adequate safeguards including the immediate availability of glucose for intravenous injection are arranged. In most cases the test will yield the correct diagnosis, but since borderline response occurs a number of further tests have been suggested.

The infusion of arginine causes a release of HGH as shown by Knopf et al. (1965) Comparative studies between the HGH release to insulin induced hypoglycaemia and to arginine infusion have been published by Parker et al (1967) and Frohman et al. (1967) The conclusion in both studies is that the arginine provocative test is a complement in the diagnosis of hyposomatotrophinism but even this test is not able to make an exact distinction in every single case. The advantage with the test is that there is no risk for hypoglycaemia.

The effect of vasopressin on HGH levels was studied by Gagliardino et al. (1967) In 15 normal subjects aged four months to 88 years an increase in HGH was measurable 30 to 60 minutes after an intramuscular injection of vasopressin In four hypopituitary patients there was no difference between HGH release to insulin or vasopressin The advantage of this test would be a single provocative test for HGH ACTH (Gwinup 1965) and FSH (Dreyfus et al 1963) However at this time the knowledge about the vasopressin test for HGH release is too small to make it useful as a routine test.

Hyperglycaemia was early shown to induce a decrease in HGH levels, followed by an increase in consequence of blood sugar decrease (Roth 1963 b) This has been studied in detail by Hunter et al (1967) who have described a simple screening test for growth hormone deficiency The increased HGH levels are studied in 2—3 blood samples taken $2^1/_2$ to 4 hours after an oral glucose load of 1 4 g per kg In patients with probable hypopituitarism they found agreement between this test and HGH response to insulin induced hypoglycaemia. The advantage of a glucose test is that it is less unpleasant for the patient and that it probably is a more physiological stimulus.

The metabolic HGH test has been used by some investigators. Prader et al (1964) showed that daily injections of 2 mg/m² of HGH increased the nitrogen retention during the 2nd and 6th day of treatment to a much greater extent in cases of pituitary dwarfism than in cases involving other causes of growth retardation Hubble (1966) showed that the withdrawal of HGH after a test period of 5—9 days induced an increase in nitrogen excretion in non hypopituitary dwarfs while hypopituitary children still retained nitrogen. These metabolic tests, however are very time demanding and require very good cooperation of the patients since nothing seems to be more difficult in practice than an accurate collection of urine.

The four patients with doubtful hypopituitarism (Cases 17 22, 23 and 25 Tables XVII and XXI) did not increase their growth velocity during the treatment. It was continued for at least 6 months since seasonal variations and transient growth accelerations may influence the results if shorter periods are studied.

Antibodies to HGH were not detectable in any patient. Six patients have had treatment for more than 1 1/2 years and two for almost four years.

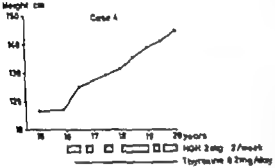

Fig 25 Growth during four years of treatment with HGH

Discussion

The treatment with HGH Roos has accelerated the growth in all patients with hypopituitarism. During the first year of treatment the growth velocity was above normal for age except for one case (no. 10) who was of normal height when the treatment began. During prolonged treatment the growth velocity decreased to a level comparable to normal growth. This should not be considered as a failure of treatment since similar growth response is seen after thyroid treatment for hypothyroidism (Talbot and Sobel 1948). The height increment during treatment in this study is of the same order as reported by others (Aarskog 1963 Raben 1964 Seip and Trygstad 1966, Tanner and Whitehouse 1967 and Prader et al. 1967) The dose of HGH used for treatment in the present study is less than the dose used in most other studies but comparable with that in the study of Rosenbloom (1966) where weekly injections of 2.5 to 5 mg were found to be effective in most patients. The immunoreactive activity of HGH Roos is slightly higher when compared to that of other preparations used for treatment and the same may be true of the biological activity as well. The absence of growth improvement in the four children of doubtful pituitary deficiency is in agreement with earlier attempts to treat other types of dwarfism. It is taken as an indication that the reason for stunted growth in these four patients is not pituitary deficiency

The most encouraging observation in the present study is the absence of antibodies to HGH.

Using HGH Raben (1959) Prader et al. (1967) reported the development of antibodies and the attendant failure to growth in eight of eighteen patients. Tanner and Whitehouse (1967) also found antibodies to HGH Raben in four of nineteen patients. Most patients developed antibodies within a year of treatment, one patient after about $1^1/_2$ years of treatment. The patient studied by Franer and Smith (1966) developed antibodies to HGH Li and Papkoff (1956) within nine months of treatment and Parker et al. (1966) reported development of antibodies to HGH Wilhelmi (1961) in one of thirteen children after seven months of treatment. The risk for development of antibodies after the first year of treatment seems to be negligible. In all studies above the patients who developed antibodies became resistant to further treatment with HGH. However Roth et al. (1964) were able to demonstrate antibodies in three of four patients with long term treatment with HGH but there was no obvious resistance to HGH therapy Kaplan et al. (1968) demonstrated HGH antibodies of low binding capacity in one-third of the patients treated for more than six months. The antibodies apparently did not affect the growth rate during treatment. A possible explanation to these differences in the effect of HGH

Treatment of pituitary dwarfism with human growth hormone

*in collaboration with Paul Roos**

The first successful treatment of a hypopituitary dwarf with human growth hormone (HGH) was reported by Raben (1958). During the following years several authors (Shepard et al. 1960, Vest et al. 1960, Escamilla et al. 1961, Aarskog 1963, Trafford et al. 1963, Soyka et al. 1964, Rosenbloom 1966, Seip and Trygstad 1966, Tanner and Whitehouse 1967, Prader et al. 1967 and Kaplan et al. 1968) have published their results on HGH therapy using various preparations. The general experience of HGH treatment, however, is limited due to lack of sufficient amounts of the hormone.

Only hypopituitary dwarfs have been proved to enhance their growth to HGH. No side effects to treatment with HGH have been reported but a limitation in the treatment is the development of antibodies to HGH. This was first shown for the Raben preparation by Széky et al. (1962). In the present investigation growth acceleration to therapy with HGH according to Roos et al. (1963) has been studied. Tests for the presence of antibodies have been performed in all patients with HGH therapy of 6 months or more.

Material and methods

Subjects. Nine patients with hypopituitary dwarfism (clinical data in Tables XVI and XX, pages 45 and 49) have been treated. Furthermore four patients with doubtful hypopituitarism (cases number 17, 22, 23, 25 in Tables XVII and XXI, pages 45 and 49) have been treated for 6 months. The clinical evaluation of the diagnosis has been described in Chapter XII.

Human growth hormone was prepared by Roos according to the method of Roos et al. (1963). The preparation was stored lyophylised and was dissolved prior to the intramuscular injection in 1 ml 0.9 % saline. The dose was for all patients 2 mg twice a week. Lack of hormone made interruptions in the treatment necessary.

Height was measured every third month during treatment and, if possible, at the same time of the day on all occasions.

HGH antibodies were determined according to the method described in Part I (Chapter VII). Blood samples were taken every six months even if an occasional interruption in the treatment had occurred. All patients were tested for the presence of antibodies in January 1968.

Results

Hypopituitarism. The results are summarized in Table XXIII and shown for case 4 in Fig. 25. The numbering of the patients refers to Tables XVI and XVII. If treatment had been continuous for all patients the height increment during the first year varied between 60 and 160 mm with a mean of 105 mm. For the second year the variation was 75—120 mm with a mean of 92 mm. Mean height increment for the following two years was for the two patients studied about 60 mm per year. No side effects to the treatment were found.

---

* Ass. Professor at the Institute of Biochemistry, University of Uppsala. *The preparation of HGH used for treatment has been supported by the Swedish Medical Research Council.*

The four patients with doubtful hypopituitarism (Cases 17, 22, 23 and 25 Tables XVII and XXI) did not increase their growth velocity during the treatment. It was continued for at least 6 months since seasonal variations and transient growth accelerations may influence the results if shorter periods are studied.

Antibodies to HGH were not detectable in any patient. Six patients have had treatment for more than 1½ years and two for almost four years.

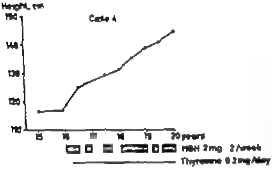

Fig. 25 *Growth during four years of treatment with HGH*

Discussion

The treatment with HGH Roos has accelerated the growth in all patients with hypopituitarism. During the first year of treatment the growth velocity was above normal for age except for one case (no. 10) who was of normal height when the treatment began. During prolonged treatment the growth velocity decreased to a level comparable to normal growth. This should not be considered as a failure of treatment since similar growth response is seen after thyroid treatment for hypothyroidism (Talbot and Sobel 1948). The height increment during treatment in this study is of the same order as reported by others (Aarskog 1963, Raben 1964, Seip and Trygstad 1966, Tanner and Whitehouse 1967 and Prader et al. 1967). The dose of HGH used for treatment in the present study is less than the dose used in most other studies but comparable with that in the study of Rosenbloom (1966) where weekly injections of 2.5 to 5 mg were found to be effective in most patients. The immunoreactive activity of HGH Roos is slightly higher when compared to that of other preparations used for treatment and the same may be true of the biological activity as well. The absence of growth improvement in the four children of doubtful pituitary deficiency is in agreement with earlier attempts to treat other types of dwarfism. It is taken as an indication that the reason for stunted growth in these four patients is not pituitary deficiency.

The most encouraging observation in the present study is the absence of antibodies to HGH.

Using HGH Raben (1959), Prader et al. (1967) reported the development of antibodies and the attendant failure to growth in eight of eighteen patients. Tanner and Whitehouse (1967) also found antibodies to HGH Raben in four of nineteen patients. Most patients developed antibodies within a year of treatment, one patient after about 1½ years of treatment. The patient studied by Fraser and Smith (1966) developed antibodies to HGH Li and Papkoff (1956) within nine months of treatment and Parker et al. (1966) reported development of antibodies to HGH Wilhelmi (1961) in one of thirteen children after seven months of treatment. The risk for development of antibodies after the first year of treatment seems to be negligible. In all studies above the patients who developed antibodies became resistant to further treatment with HGH. However Roth et al. (1964) were able to demonstrate antibodies in three of four patients with long term treatment with HGH but there was no obvious resistance to HGH therapy. Kaplan et al. (1968) demonstrated HGH antibodies of low binding capacity in one-third of the patients treated for more than six months. The antibodies apparently did not affect the growth rate during treatment. A possible explanation to these differences in the effect of HGH

antibodies could be differences in the antibody titre. A comparison can be made with insulin since most patients develop antibodies to insulin with low binding capacity and without interference of response to treatment.

The absence of antibodies in the present study is in agreement with the results of Seip and Trygstad (1966). They were not able to detect antibodies to HGH Roos in two patients after treatment for $3^1/_2$ years. The presence of antibodies was not tested in the other ten patients treated, but none developed resistance to the HGH treatment.

The reason for the finding that HGH Roos probably does not provoke the development of antibodies is not clear. No available HGH preparation is homogeneous, which has been discussed in Part I for HGH Roos. However the preparation procedure of Roos et al. is very mild, the pituitaries are initially frozen and then the material is handled only in aqueous solutions at near neutral pH and all steps are performed at 0—4°C. The extraction in glacial acetic acid and the heating to 70°C in the Raben prodedure may partly denature the hormone. Such a conformational change would be a likely explanation to the observed antigenicity.

Summary

Two mg HGH has been given twice a week to nine patients with pituitary dwarfism and to four children in whom pituitary dwarfism was suspected. All nine patients with proved hypopituitarism increased their growth velocity, the mean height increment during the first year of treatment being 10.5 cm. During the following years the growth velocity approached normal growth. None of the patients became resistant to the treatment and regular tests for antibodies were negative. None of four patients with doubtful hypopituitarism responded to the treatment.

Growth hormone levels in children during long-term treatment with corticosteroids

The administration of corticosteroids has long been known to interfere with normal growth (Blodgett et al 1956) However little is known about the mechanism of the growth inhibition Since the radioimmunoassay for growth hormone made it possible to study the hormone levels in various conditions some studies of the levels during corticosteroid treatment in adults have been published. Hartog et al (1964 b) studied seven patients with corticosteroid treatment and three patients with Cushing s syndrome. They were not able to show any differences in fasting levels of growth hormone. The increase in growth hormone after insulin induced hypoglycaemia, however was diminished for both groups of patients when compared to normal subjects. Frantz and Rabkin (1964) were able to show the same for 11 adult patients treated with long term steroid therapy in various doses Furthermore they demonstrated that the increase in growth hormone levels was less in patients receiving more than 60 mg of Cortisone or equivalent a day Treatment for two days in a dosage of 300 mg Cortisone a day gave a moderate inhibition in growth hormone response. As for children only a small series of five patients currently under long term corticosteroid treatment has been published (Root et al.

***Treatment ended 6 months before investigation

1967) The diagnosis varied in all five patients and the results are, for several reasons, difficult to evaluate.

Material and methods

Subjects Seventeen children 6 to 15 years old and with steroid treatment for 1—8½ years were investigated. The reason for steroid treatment was in all patients asthma. All patients were in a good physical condition during the investigation and none had suffered a serious asthma attack during the week immediately preceding the study. The dosage of steroids varied during the last year of treatment but the mean dosage was calculated to allow a comparison with the growth increment during the year. Steroid preparations used were Prednisone, Prednisolone and Triamcinolone but all doses are calculated in Cortisone equivalents. (5 mg Prednisone/Prednisolone equal to 4 mg Triamcinolone equal to 25 mg Cortisone). Data about the patients are summarized in Table XXIV.

Insulin tolerance test The test was performed as described earlier (page 39) with the single exception that the last blood sample was withdrawn 75 minutes after the insulin injection.

Measurements of growth Regular control of standing height was performed 3—4 times a year. The height increments are compared with the whole year velocity standards for height of Tanner et al. (1966). Fig. 26 shows the height increments for case 13.

Bone age estimations were performed by the method of Eklöf and Ringertz (1967). The X-rays were all taken by a staff with long experience of the method, all calculations of the bone age were performed by the same radiologist.

Results

The results are summarized in Table XXV and illustrated in Fig. 27 showing a normal response (case 4) and an inhibited response

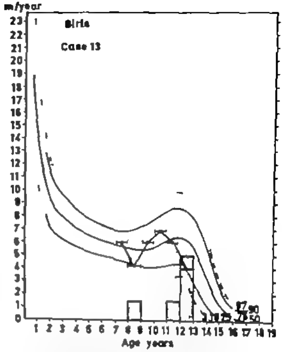

Fig. 26. Growth rate during steroid treatment. Shadowed areas indicate the dosing of Cortisone. A mean dose of 10, 10 and 23 mg Cortisone/day given during the year studied.

(case 11). In all patients the blood glucose dropped to less than 50 per cent of the resting level. Most patients showed minor discomfort during the hypoglycaemia (mild dizziness and sweating) but the test was not interrupted in any patient.

There was no difference in resting levels of growth hormone found between normal children (chapter XI) and children treated with steroids. The increase in growth hormone levels, however, was inhibited by the steroid treatment. There was a statistically significant difference ($p < 0.005$) for the HGH increments of normal children (29.1 ± 11.5 ng/ml) and those treated with corticosteroids (16.6 ± 8.2 ng/ml). There was no difference in time of growth hormone response since most patients showed maximal increment at 45 minutes, some already at 30 minutes and some at 60 minutes after the insulin gift.

Growth hormone levels in children during long term treatment with corticosteroids

The administration of corticosteroids has long been known to interfere with normal growth (Blodgett et al 1956) However little is known about the mechanism of the growth inhibition Since the radioimmunoassay for growth hormone made it possible to study the hormone levels in various conditions some studies of the levels during corticosteroid treatment in adults have been published. Hartog et al. (1964 b) studied seven patients with corticosteroid treatment and three patients with Cushing's syndrome. They were not able to show any differences in fasting levels of growth hormone. The increase in growth hormone after insulin induced hypoglycaemia, however was diminished for both groups of patients when compared to normal subjects. Frantz and Rabkin (1964) were able to show the same for 11 adult patients treated with long term steroid therapy in various doses Furthermore they demonstrated that the increase in growth hormone levels was less in patients receiving more than 60 mg of Cortisone or equivalent a day Treatment for two days in a dosage of 300 mg Cortisone a day gave a moderate inhibition in growth hormone response. As for children only a small series of five patients currently under long term corticosteroid treatment has been published (Root et al.

**Treatment ended 16 months before investigation
***Treatment ended 6 months before investigation

1967) The diagnosis varied in all five patients and the results are, for several reasons, difficult to evaluate.

Material and methods

Subjects. Seventeen children 6 to 15 years old and with steroid treatment for 1—8½ years were investigated. The reason for steroid treatment was in all patients asthma. All patients were in a good physical condition during the investigation and none had suffered a serious asthma attack during the week immediately preceding the study. The dosage of steroids varied during the last year of treatment but the mean dosage was calculated to allow a comparison with the growth increment during the year. Steroid preparations used were Prednisone, Prednisolone and Triamcinolone but all doses are calculated in Cortisone equivalents. (5 mg Prednisone/Prednisolone equal to 4 mg Triamcinolone equal to 25 mg Cortisone). Data about the patients are summarized in Table XXIV.

Insulin tolerance test. The test was performed as described earlier (page 39) with the single exception that the last blood sample was withdrawn 75 minutes after the insulin injection.

Measurements of growth. Regular control of standing height was performed 3—4 times a year. The height increments are compared with the whole year velocity standards for height of Tanner et al. (1966). Fig. 26 shows the height increments for case 13.

Bone age estimations were performed by the method of Eklöf and Ringertz (1967). The X-rays were all taken by a staff with long experience of the method, all calculations of the bone age were performed by the same radiologist.

Results

The results are summarized in Table XXV and illustrated in Fig. 27 showing a normal response (case 4) and an inhibited response

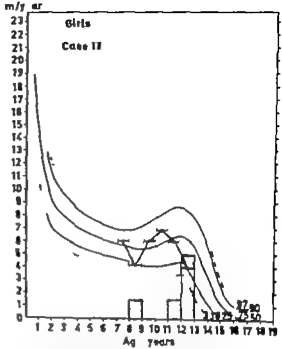

Fig. 26. Growth rate during steroid treatment. Shadowed areas indicate the dosage of Cortisone. A mean dose of 10, 10 and 23 mg Cortisone/day given during the years studied.

(case 11). In all patients the blood glucose dropped to less than 50 per cent of the resting level. Most patients showed minor discomfort during the hypoglycaemia (mild dizziness and sweating) but the test was not interrupted in any patient.

There was no difference in resting levels of growth hormone found between normal children (chapter XI) and children treated with steroids. The increase in growth hormone levels however was inhibited by the steroid treatment. There was a statistically significant difference ($p < 0.005$) for the HGH increments of normal children (29.1 ± 11.5 ng/ml) and those treated with corticosteroids (16.6 ± 8.2 ng/ml). There was no difference in time of growth hormone response since most patients showed maximal increment at 45 minutes, some already at 30 minutes and some at 60 minutes after the insulin gift.

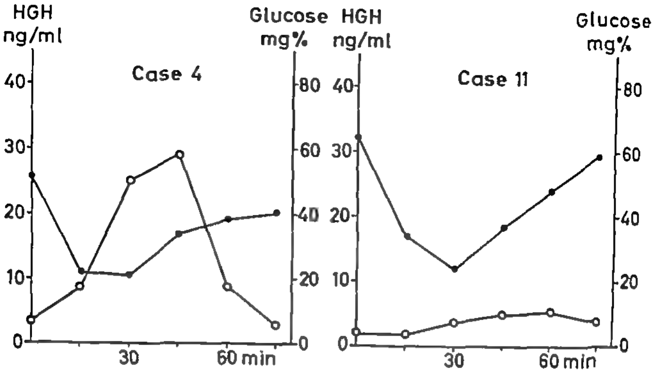

Fig 27 Blood glucose —• and HGH o—o response to insulin Normal response to the left inhibited response to the right

A correlation was sought between dosage of corticosteroids the month prior to the investigation and the maximal increment of HGH during insulin load. The result is shown in Fig 28 The correlation coefficient was —0 66 and the significance for the slope of the regression line to be different from 0 is at p <0 005 level. So there is a significant correlation between dosage of corticosteroids and increment in growth hormone during insulin load.

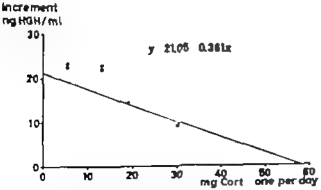

Fig 28 Correlation between increment of HGH during insulin load and dosage of Cortisone during the month prior to the study The line indicates the correlation line

It was possible to find a correlation between height increment percentile and growth hormone increase (Fig 29) The correlation coefficient is 0.52, and the significance for slope of the regression line to be different from 0 is at p <0 005 level. Yet it is very doubtful if this is a true correlation The height percentile is influenced by the steroid treatment of the previous year while the HGH increment on one occasion never can be representative for the whole year

Nothing is known about the duration of the inhibition of growth hormone release after the steroid therapy has finished and how temporal variations in steroid treatment influence the inhibition of growth hormone release. Some data indicate that the inhibition is of rather short duration If for instance instead of mean Cortisone dose during the last month the corresponding doses for the last three months are studied the correlation coefficient is about —0 32. Furthermore those patients (cases 3 and 17) who recently had finished their treatment showed normal increments. Case 9 having a very high Cortisone dosage (250 mg/day) two months

A correlation was sought between dosage of corticosteroids the month prior to the investigation and the maximal increment of HGH during insulin load. The result is shown in Fig 28 The correlation coefficient was —0 66 and the significance for the slope of the regression line to be different from 0 is at p <0 005 level So there is a significant correlation between dosage of corticosteroids and increment in growth hormone during insulin load.

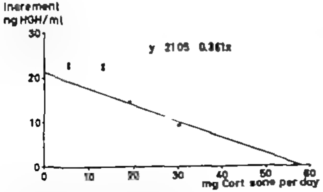

Fig 28 Correlation between increment of HGH during insulin load and dosage of Cortisone during the month prior to the study The line indicates the correlation line

It was possible to find a correlation between height increment percentile and growth hormone increase (Fig 29) The correlation coefficient is 0.52, and the significance for slope of the regression line to be different from 0 is at p <0 005 level. Yet it is very doubtful if this is a true correlation The height percentile is influenced by the steroid treatment of the previous year while the HGH increment on one occasion never can be representative for the whole year

Nothing is known about the duration of the inhibition of growth hormone release after the steroid therapy has finished, and how temporal variations in steroid treatment influence the inhibition of growth hormone release. Some data indicate that the inhibition is of rather short duration If for instance instead of mean Cortisone dose during the last month the corresponding doses for the last three months are studied the correlation coefficient is about —0.32 Furthermore those patients (cases 3 and 17) who recently had finished their treatment showed normal increments. Case 9 having a very high Cortisone dosage (250 mg/day) two months

decreased range in normal variation in the technique used by Root et al. will hide the moderate inhibition that would be expected for the comparably low dosage of corticosteroids used in the four patients in which no inhibition could be noted. In accordance with the previous findings of Frantz and Rabkin (1964) and Hartog et al. (1964 b) on adults, the results of the present study show that corticosteroids inhibit the release of growth hormone during insulin-induced hypoglycaemia even in children. The degree of inhibition is correlated to the amount of steroids.

At this time, however little is known about the mechanism of the inhibition of the pituitary function by the corticosteroids. Vernikos-Danellis (1965) has studied the corticotrophic function in rats and was able to show that Cortisone reduced the corticotrophin-releasing factor (CRF) of the median eminence in the hypothalamus. Furthermore it was shown that a dose of corticosteroids that was sufficient to inhibit stress-induced ACTH release did not affect the pituitary ACTH content. Whether the suppression is caused by influence on the regulatory system of the hypothalamus or on the synthesis of CRF is unknown.

Corresponding studies in the same animal for GH have been performed by Pecile and Müller (1966) who could show that the content of GH in the anterior pituitary was influenced by corticosteroids, whereas the amount of growth hormone releasing factor was decreased. Thus even for GH the inhibition seems to be due to some changes in the neurohumoral structures of the hypothalamus. This is in agreement with the findings of Abrams et al. (1964) who demonstrated an impairment in GH response to hypoglycaemia in squirrelmonkeys with hypothalamic lesions and with the results of Roth et al. (1963 a) who, in a patient subjected to pituitary stalk section, found that the usual response to hypoglycaemia was inhibited despite normal resting levels of growth hormone.

In most children with long term steroid treatment a retardation of the start of puberty is noted. An attractive explanation for this is inhibition in further neurohumoral functions in the hypothalamic region caused by the steroids.

Resting levels of HGH are normal even in steroid treated children and the inhibition of HGH release during hypoglycaemia, a rather unphysiological state, is not proof that this inhibition is the only or the main reason for the reduced growth in these children. Probably the effect of steroids on the hypothalamic structures is one of several factors that cause the inhibition of growth. One factor could be the katabolic action of corticosteroids *per se* resulting in a supply of protein insufficient for adequate growth. The delay in bone age could support this. Of great interest are the results of Friedman and Strang (1966) who found that the growth impairment caused by corticosteroids could be diminished if the patients were treated with a combination of corticosteroids and corticotrophin. Converting the total amount of corticosteroids to corticotrophin did enhance rather than inhibit growth. Since ACTH *per se* does not stimulate HGH secretion, the authors suggest other presently unknown adrenal steroids released by ACTH to be growth promoting factors. Several substances as yet not specifically characterised, but with typical steroid color reactions have been found in adrenal venous blood of dogs (Farrel and Lamus 1953). In practice it would look attractive to replace treatment with corticosteroids with ACTH. However only ACTH of animal origin is avialable and it has to be given in injections. Allergic reactions have been reported but are less common when highly purified ACTH is used. A synthetic α1—24-corticotrophin (Synacten® Ciba) has been introduced and this might eliminate the risk for allergic side-reactions. It would be of interest to study growth hormone increments in children treated with corticotrophin.

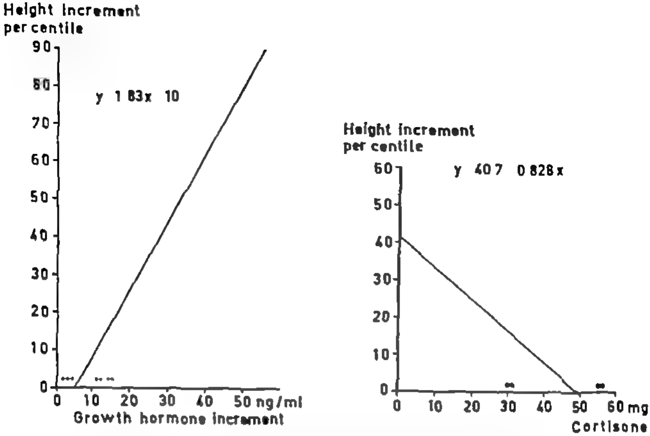

Fig 29 Correlation between height increment percentile and HGH response to insulin-induced hypoglycaemia to the left and correlation between height increment percentile and mean Cortisone dose per day during the actual year to the right. The lines indicate correlation lines

before the investigaion and a moderate dosage at the time of the experiment, shows normal growth hormone increment. It is also noted that growth inhibition is decreased if the corticosteroids are given intermittently

It would be of interest to try to correlate the mean dosage of Cortisone during the last year with the height increment during that time. This is shown in Fig. 29 The correlation coefficient is —0 68 and the significance for the slope of the regression line to be different from 0 is at p <0 005 level Furthermore it is noted that those patients who have got a mean Cortisone dosage of more than 20 mg per day during the current year have a height increment percentile of 10 or less.

The bone age was delayed in 9 of the 17 patients. Roughly all patients with delay in bone age have had a mean Cortisone dose of 7 g or more per year One patient, however (case 12) shows a moderate delay in bone age with only 2.7 g Cortisone/year another patient (case 17) got 7.3 g per year without retardation of the bone age. However that patient was 15 years old and had finished her steroid treatment six months before the X ray for the bone age determination.

Discussion

The results of the present study are not in agreement with those found in children by Root et al (1967) who were not able to show any inhibition in growth hormone release during insulin induced hypoglycaemia in four of their five Cortisone-treated patients. Results of the method of Root et al (1967) differ from the results of other methods in the measurement of HGH response to hypoglycaemia in normal children, as well. The reason for this has been discussed earlier (page 40) It is supposed that the

decreased range in normal variation in the technique used by Root et al. will hide the moderate inhibition that would be expected for the comparably low dosage of corticoster oids used in the four patients in which no inhibition could be noted. In accordance with the previous findings of Frantz and Rabkin (1964) and Hartog et al. The reason for this has been discussed earlier (page 40) It is supposed that the

Growth hormone levels during the first week of life in full term normal infants infants of diabetic mothers and in premature infants

Several authors have reported high levels of growth hormone during the neonatal period (Cornblath et al. 1965 Laron et al. 1966 and Milner and Wright 1966) However most of the data are single determinations on different patients during the actual period. Differences have been shown between premature and full-term infants (Cornblath et al. 1965) and between normal infants and infants of diabetic mothers (Laron et al. 1967) The effect on HGH levels during insulin or glucose load has been reported in isolated cases. Milner and Wright (1966) have reported the growth hormone response to hyperglycaemia induced by exchange transfusion with glucose and disodium citrate used as preservative in twentytwo cases. However exchange transfusions induce many other metabolic changes in the blood so the results are difficult to evaluate. In this study full-term normal infants and infants of diabetic mothers have been studied with insulin and glucose load during the first week of life. In addition, a small group of premature infants will be presented.

Material and methods

Data about the patients studied are shown in Table XXVI Prematurity is defined as birth weight below 2,500 g.

All infants were well at time of the study The reason for the caesarean section in the control infants was threatening obstetrical complications. There was no prolonged labor prior to the operation. The infants of diabetic mothers were routinely delivered by caesarean section.

For the study the umbilical vein was catheterized with a small polyethylene tube (Bardic[R] infant feeding tube. C. R Bard, Inc., Murray Hill U.S.A.) Blood samples were obtained from the tube and placed in glass tubes containing heparin (Vitrum, Stockholm, Sweden) Blood for glucose estimation was withdrawn immediately The samples were kept at +4 C until centrifuged. The plasma was withdrawn and frozen. To prevent clotting in the polyethylene tube 2 ml of 0.9 % saline with 10 U heparin per ml was injected after the blood sample was drawn. The first 1 ml containing blood, saline and heparin was discarded at each time interval before a blood sample was obtained.

Hypoglycaemia was induced by giving insulin intravenously through the plastic tube in a dose of 4 U/square meter body surface. A blood sample was drawn prior to the insulin load and the insulin was followed by 5 ml of 0 9 % saline. Then the polyethylene tube was replaced by a new one to avoid contamination. Blood samples were drawn every 15 minutes until 105 or 120 minutes after the insulin injection except for some of the prematures where it was impossible to withdraw such large volumes of blood.

Hyperglycaemia was induced by the injection of 0.5 g glucose/kg body weight in 15 % solution. The same precaution of changing the polyethylene tube was taken. Blood samples were collected prior to the glucose injection and at time intervals as above after injection.

The combined insulin-glucose-load was started as an ordinary insulin load, a blood sample was drawn 70 minutes after the insu-

Summary

The growth hormone increment induced by hypoglycaemia has been studied in 17 children treated with corticosteroids. No difference in fasting levels was found between normal children and Cortisone-treated children. An inhibition in HGH release due to insulin induced hypoglycaemia was found as well as a correlation between the inhibition of HGH release and dosage of corticosteroids. Furthermore a correlation between mean dose of corticosteroids per year and height increment was observed. The bone age was delayed in nine of the children all of them having high doses of steroids. The mode of the inhibition to HGH release is discussed. Reduced growth is most likely due as well to factors other than inhibition of HGH release. Despite the disadvantage in method of administration, ACTH might be tried more frequently

Growth hormone levels during the first week of life in full term normal infants, infants of diabetic mothers and in premature infants

Several authors have reported high levels of growth hormone during the neonatal period (Cornblath et al. 1965 Laron et al. 1966 and Milner and Wright 1966) However most of the data are single determinations on different patients during the actual period. Differences have been shown between premature and full-term infants (Cornblath et al. 1965) and between normal infants and infants of diabetic mothers (Laron et al. 1967) The effect on HGH levels during insulin or glucose load has been reported in isolated cases. Milner and Wright (1966) have reported the growth hormone response to hyperglycaemia induced by exchange transfusion with glucose and disodium citrate used as preservative in twentytwo cases. Despite the disadvantage in method of administration ACTH might be tried more frequently

buffer flow chromatography 25 µl of 7 % bovine serum albumin in 0.9 % saline was added to keep constant the amount of carrier protein in the buffer flow. For the standard curve 50 µl of a mixture of equal parts heparinized plasma from blood donors and albumin as above was added.

Results

The results are shown in Fig. 30—34 and summarized in Table XXVII. Statistical evaluation of the different HGH release determinations is shown in Tables XXVIII, XXIX and XXXI.

The hypoglycaemia induced by insulin was more pronounced in infants of diabetic mothers. Slightly lower levels were noticed during the first day of life for all groups of patients when compared to the end of the first week. The fall in blood glucose from the basic level was of about the same degree on both occasions studied and in all patients (Fig. 35).

The base levels of HGH are, for all patients studied, higher during the first day of life than at the age of 5—6 days. The base levels of infants of diabetic mothers are markedly lower than those of other groups. The decrease between the first day of life and the age of 5—6 days is less marked in premature infants.

*The results obtained show that the patient should be classified as an infant of a mother with gestational diabetes.

lin injection, followed by 0.5 g glucose/kg of body weight within 1 minute. The polyethylene tube was replaced by a new tube and blood samples were collected at 5, 20 and 35 minutes after the glucose gift.

The first investigation was performed between 5—24 hours of age and a second on the same patient at the age of 5—6 days. The age of the infant is the time (hours or days) that has passed since the delivery. The infants were starving before the first investigation and had been fasting about 4 hours prior to the second. To prevent infection the infants got Ampicillin[R] in doses of 50 mg/kg and day for 5 days after each umbilical catheterization. Most infants got a small transfusion of blood after the second investigation. No complications to the study have been observed. During the study the temperature of the infant decreased slightly. The decrease, however, did not exceed 1°C.

Blood glucose was estimated by a modification of the glucoseoxidase method using 0.025 M NaOH and 10 % $ZnSO_4—7\ H_2O$ as protein precipitating agents. (*Hjelm* and de Verdier 1963.)

Radioimmunoassay of growth hormone was performed by the method described in Part I with one exception. Since rather high levels of growth hormone were expected the amount of plasma in the incubation mixture was reduced from 50 µl to 25µl. Prior to the

buffer flow chromatography 25 µl of 7 % bovine serum albumin in 0.9 % saline was added to keep constant the amount of carrier protein in the buffer flow. For the standard curve 50 µl of a mixture of equal parts heparinized plasma from blood donors and albumin as above was added.

Results

The results are shown in Fig. 30—34 and summarized in Table XXVII. Statistical evaluation of the different HGH release determinations is shown in Tables XXVIII, XXIX and XXXI.

The hypoglycaemia induced by insulin was more pronounced in infants of diabetic mothers. Slightly lower levels were noticed during the first day of life for all groups of patients when compared to the end of the first week. The fall in blood glucose from the basic level was of about the same degree on both occasions studied and in all patients (Fig. 35).

The base levels of HGH are, for all patients studied, higher during the first day of life than at the age of 5—6 days. The base levels of infants of diabetic mothers are markedly lower than those of other groups. The decrease between the first day of life and the age of 5—6 days is less marked in premature infants.

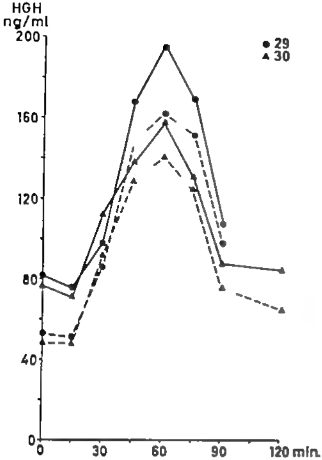

Fig 34 Growth hormone levels d ring glucose load in the first day of life —— and at the age of 5—6 days - - - in 2 premature infants Characters refer to Table XXVI

The HGH increase due to hypoglycaemia was, when expressed in absolute levels, considerably greater in the first day of life than at the end of the first week for all patients except for the premature infants. The increase was more pronounced in normal and premature infants than in infants of diabetic mothers (Table XXVIII)

If instead of absolute values of HGH, the per cent maximal increment from the basic levels at the start of the experiment are compared, this increase seems to be of about the same degree for all patients except for the premature infants. These 3 patients increased their increment at the end of the first week when compared to the first day of life. The statistical evaluation is summarized in Table XXIX

The effect of hyperglycaemia was studied in two different experiments which makes it difficult to compare the patients. The blood glucose levels in the single glucose loads are shown in Fig 36 The glucose disappearance rate (K_G)* is shown in the figure. It is slightly higher for normal infants than for prematures In the infants of diabetic mothers the glucose load was added to the insulin load and this was also performed on three normal infants. The rate of glucose disappearance (k_G) for these patients is summarized in Table XXX.

The HGH levels increased during hyperglycaemia in all patients, the increase in absolute levels being more pronounced during the first day of life. The increase was higher for premature infants at the end of the first week than for normal infants. Statistical evaluation is shown in the upper part of Table XXXI If instead of increase in absolute levels the per cent maximal increment is studied the increase seems to be more pronounced at the end of the first week for prematures while other patients studied do not show any difference. The statistical evalution is shown in the lower part of Table XXXI

Of special interest is case number 10 Her HGH levels during the whole study are in better agreement with those of infants of diabetic mothers than with those of normal infants. She is the second child of the mother the first child having a birth weight of 4 680 g A glucose tolerance test on the mother one month after delivery of the first child showed a glucose disappearance rate (k_G) of 1 01

Discussion

The paucity of data on HGH levels in the neonatal period and the wide variations in individual HGH response make the evaluation of the results difficult

The high base levels during the first day of life were initially believed to depend on placental transfer of human placental lactogen (HPL) a substance with hormonal activity present in maternal serum in amounts that at term are about 1 000 times those of HGH (Kaplan and Grumbach 1963) HPL crossreacts to some degree with HGH antiserum and would in part be measured in the immunoassay as HGH. However Beck et al (1965) have shown with a specific immunoassay for HPL that cord blood contains hardly measurable amounts of HPL.

Studies of HGH response to hypoglycaemia have been performed earlier in only four normal infants and two premature infants during the first day of life (Cornblath et al 1965)

The results are in agreement with those found in the present study. No infants of diabetic mothers have been studied and it is interesting that gestational diabetes seems to provoke changes in HGH response similar to those found in infants of diabetic mothers.

Hyperglycaemia has been studied in eight infants with a continuous glucose infusion (Cornblath et al. 1965) and during exchange transfusion by Milner and Wright (1966). Thus the experiments are not quite comparable. However all studies have shown an increase in HGH levels to hyperglycaemia during the neonatal period contrary to the findings at the age of 15 days or more (Cornblath et al. 1965).

The role of growth hormone during the neonatal period is not clearly understood. It does not seem to be indispensable as a growth promoting factor during the neonatal period since anencephalic human infants, even when born without a pituitary gland, have large, well-proportioned bodies (Seckel 1960). Furthermore the administration of growth hormone in premature infants does not accelerate the bone growth (*Chiumello et al. 1965*).

The *finding that HGH levels in newborn infants are higher than those of the mother* (Laron et al. 1966) *indicate an active secretion of hormone by the foetus.* Kaplan and Grumbach (1962) have demonstrated growth hormone in the pituitary gland of a 15 week foetus. The disappearance of growth hormone was studied (Cornblath et al. 1965) by *intra*venous administration of the hormone to newborn infants. The average $T^{1}/_{2}$ was 12.7 minutes compared with about 25—30 minutes for adults (page 29). So the high values obtained during the neonatal period are not due to slower plasma clearance.

For adults the main function of growth hormone seems to be homeostasis of energy providing substrates by its lipolytic action. If the energy requirements can be met by carbohydrates, secretion of growth hormone is not demanded. Glick et al. (1965) demonstrated that the normal prompt rise in HGH to insulin induced hypoglycaemia was prevented by a simultaneous administration of glucose. The subsequent fall in blood glucose after glucose administration led to a rise in HGH which was correlated in time with the secondary rise in plasma free fatty acids (FFA) after an oral glucose load. (Bolinger et al. 1962). There is no correlation between the absolute levels of blood glucose and growth hormone secretion since even very small changes in blood glucose induced by infusion of small amounts of insulin over an hour causes a marked rise in plasma HGH (Luft et al. 1966). Prolonged fasting, particularly in conjunction with exercise, increases the growth hormone levels (Hunter and Rigal 1966). Even here the effect of growth hormone will be energy homeostasis by lipolysis.

The intravenous administration of large amounts of some amino-acids, particularly arginine, is another stimulus of growth hormone secretion (Knopf et al. 1965). Arginine infusion induces an increase in plasma insulin but the blood glucose levels are not influenced. This indicates a collaboration of insulin and growth hormone in the incorporation of amino-acids into protein, a further physiological activity of growth hormone. The first evidence for the effect of growth hormone on protein synthesis in man were shown by Bech *et al. (1957)*. Growth hormone seems to stimulate the transfer of amino-acids from the extracellular to the intracellular compartments (Knobil and Hotschkiss 1964).

Whether these two actions of growth hormone, the lipolytic and the protein synthesizing, are due to action of the same molecule, the one-factor hypothesis (Raben 1965), or due to the two-factor hypothesis of Levine and Luft (1964) which suggest that the so called growth hormone of the anterior pituitary is composed *of two components*, one somatotrophic *with* the protein synthesizing effect and one adipokinetic *with the* lipolytic effect, is yet to be proved. According to the hypothesis of Levine and Luft the immunoassay of HGH will measure both effects.

Supporting the two-factor hypothesis are the results of Trygstad (1967) which have been discussed in Part I page 32

These fundamental functions of growth hormone can explain most of the results of the insulin loads in this study The new environment is energy-consuming and blood sugar decreases during the first 24 hours (Cornblath et al 1961) Person and Gentz (1966) have shown that there is an increase in FFA from rather low levels in cord blood to very high levels within the first 48 hours of life. The high levels remain during the neonatal period. When blood glucose is depressed by insulin growth hormone, by its lipolytic action might be the main regulator to energy homeostasis and consequently increases dramatically When feeding has started the demand for energy from FFA is less important which would explain the more moderate HGH levels at the age of 5—6 days.

However there is no difference in per cent maximal increment between the first and the second period investigated so the lower levels as well could be the result of a successive adaptation to a lower level of growth hormone with increasing maturity of the infant. This also could be an explanation for the results obtained in premature infants their higher degree of immaturity resulting in a slower adaption However for premature infants another factor might be of importance. Blood glucose levels during the neonatal period are lower for prematures compared to full term infants (von Euler et al 1964) The main reason for this would be the markedly lower stores of glycogen until the 37th week of gestation (Shelley and Neligan 1966) The energy demand has to be supplied from other sources, the elevated growth hormone levels raise the FFA levels. For the present weight group Melichar et al. (1964) have shown moderately elevated levels of FFA

As for infants of diabetic mothers they have decreased blood glucose levels during the neonatal period (Pedersen et al 1954) the reason for this being a rapid disposal of glucose from the blood due to hyperinsulinism (Baird and Farquhar 1962) The FFA in infants of diabetic mothers are lower when compared to those in normal infants (Chen et al 1965 and Laron et al 1967) which might be the effect of the functional hyperinsulinism and/or the low HGH values. The most likely explanation for most of the metabolic abnormalities in the infant of diabetic mothers is the maternal hyperglycaemia (Pedersen et al 1954) The better the control of the diabetes of the mother the lower the body weight and fewer symtoms of altered metabolism in the child (Pedersen 1967) A possible hypothesis is that the variations in blood glucose during gestation will increase the demands on the regulatory system The latter might improve and be more mature. Therefore the resting levels would be closer to those found in older infants. Exhaustion of the pituitary or regulary system because of large demands during foetal life would give beside a low basic level a depressed response to hypoglycaemia, which has not been shown.

More difficult to explain is the paradoxical increase in growth hormone after induced hyperglycaemia. Cornblath et al. (1965) have shown that this effect remains about 14 days in full term infants and they have suggested different manners for hypo- and hyperglycaemia to trigger the secretion of growth hormone, and that the pathway for suppression requires time after birth to mature. In all groups of patients in this study (full term infants infants of diabetic mothers and prematures) an increase in growth hormone is induced by hyperglycaemia, most pronounced in prematures. This could fit the hypothesis of Cornblath et al. (1965) Another but more venturous possibility is that in newborn infants even a transient hyperglycaemia is a signal for protein synthesis. Growth hormone is necessary for that and protein synthesis and growth are never as intense as in the neonatal period. A support for this hypothesis would be the significantly greater increase in HGH levels induced by glucose load for prematures

at the age of 5—6 days when compared to the first day of life.

If one accepts the two-factor hypothesis of Levine and Luft (1964) there is another possibility. During insulin load the adipokinetic component is produced in high levels to provoke lipolysis. When glucose increases during glucose load the protein synthesizing somatotrophic component increases. It would be of great interest to repeat the estimations with an immunoassay-system for the two components described by Trygstad (1967).

Stress is another factor proved to increase growth hormone levels (Greenwood and Landon 1966). The stress of labor resulting in elevated levels of 17-OH corticosteroids (Migeon et al. 1956) affects neither the basic levels of growth hormone nor the release of growth hormone by insulin load since there are no differences between the infants delivered by caesarean section and those delivered spontaneously. However the experiment *per se* with the catheterization of the umbilical vein, the moderate lowering of the body temperature and the infusion within 1 minute of a volume which for the glucose load constitutes about 10 % of the blood volume, are stressing factors that might stimulate HGH secretion.

At this time too little is known about factors concerning the neonatal metabolism to give an entire explanation about the fundamental role of growth hormone during this period.

Summary

Growth hormone levels during insulin and glucose load have been studied in normal infants, infants of diabetic mothers and in premature infants during the first week of life.

Base levels of HGH were elevated in all patients when compared to older infants. The highest levels were present on the first day of life. Lower levels were found in infants of diabetic mothers than in the other patients studied.

Insulin-induced hypoglycaemia increased HGH levels in all patients. The increase was more pronounced at the age of one day as compared to 5—6 days if the absolute levels were compared. The increase was more moderate in infants of diabetic mothers. If the response to hypoglycaemia is expressed as the per cent maximal increment from basic levels no difference in response can be shown between the first day of life and the age of 5—6 days or between normal infants and infants of diabetic mothers. For premature infants the response in per cent increment was more pronounced at the end of the first week and of much higher degree than for other infants studied.

Hyperglycaemia induced an increase in HGH levels comparable to that found during hypoglycaemia. The differences between the groups studied are the same as for hypoglycaemia.

Supporting the two-factor hypothesis are the results of Trygstad (1967) which have been discussed in Part I page 32

These fundamental functions of growth hormone can explain most of the results of the insulin loads in this study The new environ ment is energy-consuming and blood sugar decreases during the first 24 hours (Corn blath et al 1961) Person and Gentz (1966) have shown that there is an increase in FFA from rather low levels in cord blood to very high levels within the first 48 hours of life. The high levels *remain during the neonatal* period. When blood glucose is depressed by insulin, growth hormone by its lipolytic action might be the main regulator to energy homeostasis and consequently increases dra matically When feeding has started the demand for energy from FFA is less important which would explain the more moderate HGH levels at the age of 5—6 days.

However there is no difference in per cent maximal increment between the first and the second period investigated, so the lower levels as well could be the result of a successive adaptation to a lower level of growth hor mone with increasing maturity of the infant. This also could be an explanation for the results obtained in premature infants, their higher degree of immaturity resulting in a slower adaption. However for premature in fants another factor might be of importance. Blood glucose levels during the neonatal period are lower for prematures compared to full term infants (von Euler et al 1964) The main reason for this would be the markedly lower stores of glycogen until the 37th week of gestation (Shelley and Neligan 1966) The energy demand has to be supplied from other sources, the elevated growth hor mone levels raise the FFA levels. For the present weight group Melichar et al. (1964) have shown moderately elevated levels of FFA.

As for infants of diabetic mothers they have decreased blood glucose levels during the neonatal period (Pedersen et al 1954) the reason for this being a rapid disposal of glu cose from the blood due to hyperinsulinism (Baird and Farquhar 1962) The FFA in infants of diabetic mothers are lower when compared to those in normal infants (Chen et al. 1965 and Laron et al. 1967) which might be the effect of the functional hyper insulinism and/or the low HGH values. The most likely explanation *for most of the meta* bolic abnormalities in the infant of diabetic mothers is the maternal hyperglycaemia (Pedersen et al 1954) The better the control of the diabetes of the mother the lower the *body weight and fewer symtoms* of altered metabolism in the child (Pedersen 1967) A possible hypothesis is that the variations in blood glucose during gestation will increase the demands on the regulatory system. The latter might improve and be more mature. Therefore the resting levels would be closer to those found in older infants. Exhaustion of the pituitary or regulary system because of large demands during foetal life would give, beside a low basic *level* a depressed response to hypoglycaemia, which has not been shown.

More difficult to explain is the paradoxical increase in growth hormone after induced hyperglycaemia. Cornblath et al. (1965) have shown that this effect remains about 14 days in full term infants and they have suggested different manners for hypo- and hypergly caemia to trigger the secretion of growth hor mone and that the pathway for suppression requires time after birth to mature. In all groups of patients in this study (full term infants infants of diabetic mothers and prematures) an increase in growth hormone is induced by hyperglycaemia most pronounced in prematures. This could fit the hypothesis of Cornblath et al (1965) Another but more venturous possibility is that in newborn infants even a transient hyperglycaemia is a signal for protein synthesis. Growth hormone is necessary for that and protein synthesis and growth are never as intense as in the neonatal period A support for this hypothesis would be the significantly greater increase in HGH levels induced by glucose load for prematures

I wish to express my sincere thanks to

Professor Bo Vahlquist, Head of the Department of Paediatrics for his encouraging and stimulating interest in the investigation.

Professor Gösta Hultquist, Head of the Institute of Pathology I for his interest and for the laboratory facilities placed at my disposal.

Professor Carl Gemzell, Head of the Department of Gynecology and Obstetrics, who introduced me to the interesting subject human growth hormone, and for his valuable support and advice during the course of the investigation.

Ass. Professor Jan Thorell who introduced me to the immunoassay technique and for stimulating discussion and criticism.

Ass. Professor Paul Roos for the preparation of HGH used in the investigation.

Ass. Professor Sven Kraepelin for his help in selecting most of the patients in the investigation of corticosteroid treated children.

Ass. Professors Lars Wranne and Leif Wide for helpful discussion and criticism.

Dr Gunnar Wikstrom, Department of Diagnostic Radiology University Hospital of Uppsala for the bone age estimations.

My colleagues at the Department of Paediatrics and in the Institute of Pathology I for help and friendly discussions.

Miss Britt Marie Lidman for excellent technical assistance.

Miss Kerstin Sjöberg and Mrs Monica Johnsson for their skilful typing of the manuscript.

Nursing and laboratory staff at the Department of Paediatrics for help and interest.

The investigation was supported by grants from the Medical Faculty of the University of Uppsala, the Swedish Society of Medical Research, Stockholm the Sven Jerring Foundation, Stockholm the Research Fund of Första Majblommans Riksförbund Göteborg and the Medical Research Fund of the Swedish Life Insurance Societies, Stockholm

The preparation of growth hormone used for treatment of the patients has been supported by the Swedish Medical Research Council.

General Summary

PART I

Methodological studies

A radioimmuno-chromatographic assay for human growth hormone (HGH) is described The method has been carefully tested with special reference to the influence of degradation damage of HGH and to the method's applicability to neonatal plasma Recovery experiments have been performed and the precision and sensitivity of the method is comparable with other radioimmunoassays for HGH. The method has been tested clinically and the results are comparable with those obtained by similar methods.

The radioimmuno-chromatorographic technique can be used for the detection of antibodies to HGH.

PART II

Clinical studies

1 The HGH release to insulin induced hypoglycaemia has been studied in 16 normal children and the normal response has been defined as an increase in HGH levels of 10 ng/ml or more.

2 The HGH release in children of short stature has been studied in order to diagnose hypopituitary dwarfism. The HGH release in ten children with proved hypopituitarism was subnormal as defined above Two of fifteen patients without pituitary deficiency showed subnormal response. Five children with Turner's syndrome and two with chondrodystrophic nanism showed a normal HGH response. The HGH response to the insulin tolerance test has been compared with other available tests for the evaluation of pituitary function.

3 Nine hypopituitary dwarfs have been treated with human growth hormone The height increment during the first year of treatment varied between 6 and 16 cm with a mean of 10 5 cm During the second year of treatment the mean was 9 2 cm. No patient became resistant to the treatment and regular tests for the presence of antibodies to HGH were not able to reveal any

4 Seventeen children with long term treatment with corticosteroids for bronchial asthma were investigated for HGH release to insulin induced hypoglycaemia. The response was found to be decreased when compared to normal children and a correlation coefficient of —0 66 was found between dose of corticosteroids and HGH increment.

5 Thirty newborn infants were investigated during the first day of life and at the age of 5—6 days Normal infants, infants of diabetic mothers and premature infants showed elevated fasting levels and a vigorous increase in HGH levels during hypoglycaemia as well as during hyperglycaemia The increase was more pronounced during the first day of life and more moderate in infants of diabetic mothers There was no difference in per cent increment from base levels between normal infants and infants of diabetic mothers. For premature infants the per cent increment was greater compared to the other two groups and was most pronounced at the end of the first week of life. The results are discussed with references to fat and carbohydrate metabolism during the first week of life.

INTRODUCTION

Successful transition from intra- to extrauterine life is dependent on the readjustment of a great number of functions to be accomplished more or less urgently during and following delivery. Among these adaptative processes the most dramatic changes are those occurring in the circulatory and respiratory system. The readjustment processes occurring in these two systems are intimately linked together and interdependent.

In the fetus gas exchange is exclusively achieved with the maternal circulation by means of the placenta. The lungs do not contain any gas. However the alveoli are all open to some degree (Potter 1953 Plank 1967) and appear at term to be equally expanded with liquid (Plank, 1967). This liquid differs in pH, total osmolality total CO_2 protein, sugar urea and electrolyte concentration from amniotic fluid (Adams et al., 1963 a Adams et al. 1963 b). These differences and persisting liquid formation despite artificially induced tracheal obstruction (Carmel et al., 1965) suggest that it may be an ultrafiltrate of blood, with selective reabsorption or secretion by the lung (Adams et al., 1963 b). There is an open communication between the alveoli and the surrounding amniotic fluid (Potter 1953). Intrauterine respiratory movements may occur (cf. Smith 1959) but do not seem to be a regular event. As gestation proceeds, they become rarer and the stimuli producing them are less effective.

Blood flow through the lungs is low. In the sheep fetus at term only about 12 per cent of the total cardiac output goes to the lungs (Dawes 1958). Marked fluctuations due to changes in vasomotor tone and probably related to among other factors blood gas composition, may however occur (Dawes and Mott, 1962 Cook et al., 1963).

The low pulmonary perfusion is due to high vascular resistance in the pulmonary circulation in relation to the resistance in the systemic placental circulation and most of the blood in the pulmonary trunk is deflected through the ductus arteriosus into the descending aorta. In the fetal lamb at term more than 50 per cent of the total aortic flow comes directly from the right ventricle and passes through the ductus arteriosus (Dawes et al., 1953). The left atrium mainly receives blood directly from the inferior vena cava through the foramen ovale. Thus the blood by passes the high-resistance pulmonary circuit, and both ventricles work in parallel behaving as a functionally single ejection system pumping blood into the low resistance systemic placental circulation (Lind and Wegelius, 1954 Lind 1965). In the lamb more than 50 per cent of the combined output is directed to the placenta (Dawes 1958).

When the placental circulation is eliminated at birth the inactive fetal lungs have to take over the function of the placenta as an effective gas exchanger to ascertain sur

INTRODUCTION

Successful transition from intra- to extrauterine life is dependent on the readjustment of a great number of functions to be accomplished more or less urgently during and following delivery. Among these adaptative processes the most dramatic changes are those occurring in the circulatory and respiratory system. The readjustment processes occurring in these two systems are intimately linked together and interdependent.

In the fetus gas exchange is exclusively achieved with the maternal circulation by means of the placenta. The lungs do not contain any gas. However the alveoli are all open to some degree (Potter 1953 Plank 1967) and appear at term to be equally expanded with liquid (Plank 1967) This liquid differs in pH, total osmolality total CO_2 protein, sugar urea and electrolyte concentration from amniotic fluid (Adams et al., 1963 a Adams et al., 1963 b) These differences and persisting liquid formation despite artificially induced tracheal obstruction (Carmel et al. 1965) suggest that it may be an ultrafiltrate of blood, with selective reabsorption or secretion by the lung (Adams et al 1963 b) There is an open communication between the alveoli and the surrounding amniotic fluid (Potter 1953) Intrauterine respiratory movements may occur (cf Smith, 1959) but do not seem to be a regular event. As gestation proceeds they become rarer and the stimuli producing them are less effective.

Blood flow through the lungs is low In the sheep fetus at term only about 12 per cent of the total cardiac output goes to the lungs (Dawes 1958) Marked fluctuations due to changes in vasomotor tone and probably related to among other factors blood gas composition, may however occur (Dawes and Mott, 1962 Cook et al., 1963)

The low pulmonary perfusion is due to high vascular resistance in the pulmonary circulation in relation to the resistance in the systemic-placental circulation, and most of the blood in the pulmonary trunk is deflected through the ductus arteriosus into the descending aorta. In the fetal lamb at term, more than 50 per cent of the total aortic flow comes directly from the right ventricle and passes through the ductus arteriosus (Dawes et al 1953) The left atrium mainly receives blood directly from the inferior vena cava through the foramen ovale. Thus the blood by-passes the high-resistance pulmonary circuit, and both ventricles work in parallel behaving as a functionally single ejection system pumping blood into the low resistance systemic placental circulation (Lind and Wegelius 1954 Lind, 1965) In the lamb more than 50 per cent of the combined output is directed to the placenta (Dawes 1958)

When the placental circulation is eliminated at birth the inactive fetal lungs have to take over the function of the placenta as an effective gas exchanger to ascertain sur-

MATERIAL

Since the purpose of the present investigation was to analyse normal neonatal respiratory function, the subjects of the different studies are fullterm infants who were selected at random. With but a few exceptions the infants had a spontaneous vertex delivery and were normal as regards pregnancy gestational age, labour birth weight, onset of respiration and clinical course during the neonatal period. The cord was in general clamped after cessation of visible pulsations. However case No. 71 (I) had a somewhat delayed first breath, No. 78 (I) a birthweight of only 2360 g. Study II and III include some otherwise healthy prematures with a birth weight between 1290 and 2180 g. Two cases required earlier clamping because the cord was ruptured during the delivery (II) or was twisted around the neck (VI)

No analgesia was used during labour in the first series of studies (I II III) however a chloroform anaesthesia of very short duration was given at the end of the delivery and some of the mothers received intermittent nitrous oxide during contractions during the latter part of labour In the second group of infants (IV V VI) most mothers received nitrous oxide or trichlorethylene or both by inhalation of short duration at the end of the delivery

A total of 172 infants were studied.

vival in the new enviroment. This requires

1) the more or less immediate expansion and aeration of the lungs and opening up of the pulmonary circulation

2) the continued ventilation of the opened alveoli and establishment of an adequate perfusion of the pulmonary vascular bed

3) the adjustment of distribution of alveolar ventilation and perfusion to each other and establishment of sufficient capacity for diffusion of the respiratory gases through the alveolar-capillary membrane.

The transition to extrauterine life thus implies the establishment of a new autonomic function — that of pulmonary respiration, and important changes in the distribution of cardiac output.

The present series of studies was performed to elucidate some of the mechanisms involved in this establishment and to evaluate the efficiency of lung function in the healthy fullterm newborn infant. It is mainly a study of mechanics of breathing aeration of the lungs in terms of functional residual capacity pulmonary ventilation and diffusion, efficiency of gas exchange in terms of arterial blood gases and alveolar arterial oxygen tension gradients and acid base balance Emphasis is laid on development of function. Since available reports of neonatal lungfunction studies are mainly focused on the first minutes and hours of extrauterline life the present studies have been extended to include the entire first week of life.

Respiratory problems present the major threats to survival of the newborn infant (Driscoll and Smith, 1962) They are overwhelmingly the consequence of the infant's failure to complete successfully the respiratory and circulatory adaptation from intra to extrauterine life. Knowledge of the physiological conditions underlying the normal neonatal respiration and its adjustment is a prerequisite for evaluation of the failing mechanisms and for all rational therapeutic measures. Thus all studies aiming at increasing our knowledge of the respiratory and circulatory adjustment have had and continue to have direct practical clinical implications It was under this conception that the reported studies were commenced and conducted.

The need for miniaturization of methods and apparatus and the complete lack of cooperation of the subject to be studied are serious problems to be overcome in pulmonary function investigation in the neonatal period therefore methodological details and reproducibility of methods have been emphasized.

MATERIAL

Since the purpose of the present investigation was to analyse normal neonatal respiratory function, the subjects of the different studies are fullterm infants who were selected at random. With but a few exceptions, the infants had a spontaneous vertex delivery and were normal as regards pregnancy gestational age, labour birth weight, onset of respiration and clinical course during the neonatal period. The cord was in general clamped after cessation of visible pulsations. However case No 71 (I) had a somewhat delayed first breath, No. 78 (I) a birthweight of only 2360 g. Study II and III include some otherwise healthy prematures with a birth weight between 1290 and 2180 g. Two cases required earlier clamping because the cord was ruptured during the delivery (II) or was twisted around the neck (VI)

No analgesia was used during labour In the first series of studies (I II III) however a chloroform anaesthesia of very short duration was given at the end of the delivery and some of the mothers received intermittent nitrous oxide during contractions during the latter part of labour In the second group of infants (IV V VI) most mothers received nitrous oxide or trichlorethylene or both, by inhalation of short duration at the end of the delivery

A total of 172 infants were studied.

METHODS*)

This survey gives only an enumeration of the methods used For a more detailed description the reader is referred to the original papers

MECHANICS OF BREATHING AND PULMONARY VENTILATION (I, II, III)

Tidal volume (V_T) and respiratory rate (f) were determined by means of a »reverse» body plethysmograph, connected to the infant by a face mask (III Karlberg, Cherry Escardó and Koch 1960) The volume changes were recorded by means of an inductive pressure transducer amplifier unit (Elema Schönander) on an ECG direct recorder (Mingograph 42) Flow rate (V) was derived from the volume curve by means of a specially designed electronic device (Karlberg, Cherry Escardó and Koch 1960)

Intraoesophageal pressure was recorded by means of a liquid filled polyethylene catheter 1 mm inside diameter with several holes near the tip over another pressure transducer amplifier unit on a third channel of the Mingograph

FUNCTIONAL RESIDUAL CAPACITY (FRC) (III)

The FRC was determined by means of the closed-circuit method with helium as test gas A nasal coupling was used for connecting the infant to the breathing system.

STEADY STATE PULMONARY VENTILATION AND DIFFUSING CAPACITY (VI)

The breathing circuit used was built according to the box balloon principle and consisted mainly of a glas box serving as a »reverse» plethysmograph enclosing the inspiratory and expiratory bag The respiratory pressure variations were recorded on a Mingograph 42 as described above

A low resistance gravity independent breathing valve was developed. The dead space was 0 8 and ca. 1 7 ml when used in connection with a nasal coupling and a face mask respectively

The *pulmonary diffusing capacity* was determined with the steady state carbon monoxide method (Filley et al 1954) as modified by Linderholm (1957) and calculated from the equation

$$D_{LCO} = \dot{V}_{CO} / (P_{ACO} - P_{\bar{c}CO}) \quad (1)$$

The *pulse rate* was calculated from the simultaneously recorded ECG

Effect of the investigation procedure on the infants basal state No significant changes either in respiratory or in heart rate were induced by application of the breathing mask Pa_{CO_2} ($p < 0.001$) and standard bicarbonate ($p < 0.05$) were however slightly higher and pH ($p < 0.001$) and Pa_{O_2} ($p > 0.05$) slightly lower during than before the sampling procedure During the sampling

*) Symbols used are those suggested in report in Fed Proc. 9 602, (1950)

period itself respiratory and heart rate were virtually unchanged.

The *reproducibility* of the most important data measured and calculated in connection with the determination of DLCO, when examinations at 24 hours and 7 days respectively are considered as duplicate determinations, were in the same order as in resting adults (Table IV)

VENOUS ADMIXTURE (V VI)

Venous admixture (Qs/Q) was calculated from the classical shunt formula after due transformations with the assumption of an unchanged arterial mixed venous oxygen difference of 3.5 ml/100 ml blood during both air and 100 per cent oxygen breathing and during the period of observation.

1) *Total venous admixture or physiologic shunt* (including both anatomic shunt and venous admixture from alveoli with low ventilation/perfusion ratio was estimated during air breathing from the formula

$$\frac{Qs}{Q}\ (\text{air}) = \left[1 + \frac{3.5}{O_2\text{cap}\ (S_{C}O_2 - S_aO_2) + 0.0031\ (P_{A}O_2 - P_aO_2)}\right]^{-1} 100\ (\text{per cent}) \quad (2)$$

where 0 0031 is the amount of oxygen physically dissolved in 100 ml blood per mm Hg (V VI)

2) *Venous admixture due to anatomic right-to-left shunt* was estimated during breathing of pure oxygen after washing-out of nitrogen. Oxygen breathing was performed during 20 minutes in a specially constructed plexiglass hood approximately fitting the infant s head.

Provided arterial $PO_2 > 150$ mm Hg, at which tension hemoglobin may be considered completely saturated the equation used was

$$\frac{Qs}{Q}\ (\text{oxygen}) = \left[1 + 1129/(P_{A}O_2 - P_aO_2)\right]^{-1} 100\ (\text{per cent}) \quad (3)$$

When P_aO_2 was below 150 mm Hg equation (3) was not considered to be valid and the following equation was used

$$\frac{Qs}{Q}\ (\text{oxygen}) = \left[1 + \frac{3.5}{O_2\text{cap}\ (1 - S_aO_2) + 0.0031\ (P_{A}O_2 - P_aO_2)}\right]^{-1} 100\ (\text{per cent}) \quad (4)$$

A nomogram for the PO_2 ranges above and below 150 mm Hg permitting easy estimation of anatomic shunt (Qs/Q) from arterial oxygen tension during breathing of 100 per cent oxygen is given in Fig. 1

Cardiac output (Q) (VI) was estimated from the actually measured oxygen consumption (VO_2) and the assumed value of 3.5 ml/100 ml blood for the arterial – mixed venous oxygen difference using Fick s formula

$$Q = (VO_2/3.5)\quad 100\ (ml) \quad (5)$$

BLOOD COLLECTION (IV V VI)

Since capillary blood is not a reliable substitute for arterial blood during the neonatal period particularly with respect to PO_2 (Koch and Wendel 1967 a) arterial blood had to be collected. In order to avoid disturbance of steady state conditions blood sampling had to be performed by means of an indwelling arterial catheter

Arterial blood was sampled from the descending aorta by means of a polyvinyl ca

The breathing circuit used was built according to the box balloon principle and consisted mainly of a glas box serving as a »reverse» plethysmograph enclosing the inspiratory and expiratory bag The respiratory pressure variations were recorded on a Mingograph 42 as described above

A low resistance gravity independent breathing valve was developed. The dead space was 0 8 and ca. 1 7 ml when used in connection with a nasal coupling and a face mask respectively

The *pulmonary diffusing capacity* was determined with the steady state carbon monoxide method (Filley et al 1954) as modified by Linderholm (1957) and calculated from the equation

$$D_{LCO} = \dot{V}_{CO} / (\bar{P}_{ACO} - \bar{P}_{cCO}) \quad (1)$$

The *pulse rate* was calculated from the simultaneously recorded ECG

Effect of the investigation procedure on the infants basal state No significant changes either in respiratory or in heart rate were induced by application of the breathing mask Pa_{CO_2} ($p < 0 001$) and standard bicarbonate ($p < 0 05$) were, however slightly higher and *pH* ($p < 0 001$) and Pa_{O_2} ($p > 0 05$) slightly lower during than before the sampling procedure During the sampling

*) Symbols used are those suggested in report in Fed. Proc. 9 602, (1950)

period itself respiratory and heart rate were virtually unchanged.

The *reproducibility* of the most important data measured and calculated in connection with the determination of D_{LCO} when examinations at 24 hours and 7 days respectively are considered as duplicate determinations were in the same order as in resting adults (Table IV)

VENOUS ADMIXTURE (V VI)

Venous admixture (Q_s/Q) was calculated from the classical shunt formula after due transformations with the assumption of an unchanged arterial – mixed venous oxygen difference of 3.5 ml/100 ml blood during both air and 100 per cent oxygen breathing and during the period of observation.

1) *Total venous admixture or physiologic shunt* (including both anatomic shunt and venous admixture from alveoli with low ventilation/perfusion ratio was estimated during air breathing from the formula

$$\frac{Q_s}{Q}\ (\text{air}) = \left[1 + \frac{3.5}{O_2\text{cap}\ (S_{c}\,O_2 - S_aO_2) + 0.0031\ (P_{AO_2} - P_{aO_2})}\right]^{-1} 100\ (\text{per cent}) \quad (2)$$

where 0 0031 is the amount of oxygen physically dissolved in 100 ml blood per mm Hg (V VI)

2) *Venous admixture due to anatomic right-to-left shunt* was estimated during breathing of pure oxygen after washing-out of nitrogen. Oxygen breathing was performed during 20 minutes in a specially constructed plexiglass hood approximately fitting the infant s head.

Provided arterial $P_{O_2} > 150$ mm Hg, at which tension hemoglobin may be considered completely saturated, the equation used was

$$\frac{Q_s}{Q}\ (\text{oxygen}) = \left[1 + 1129/(P_{AO_2} - P\ O_2)\right]^{1} 100\ (\text{per cent}) \quad (3)$$

When $P\ O_2$ was below 150 mm Hg equation (3) was not considered to be valid and the following equation was used

$$\frac{Q_s}{Q}\ (\text{oxygen}) = \left[1 + \frac{3.5}{O_2\text{cap}\ (1 - S_{aO_2}) + 0.0031\ (P_{AO_2} - P_{aO_2})}\right]^{-1} 100\ (\text{per cent}) \quad (4)$$

A nomogram for the P_{O_2} ranges above and below 150 mm Hg permitting easy estimation of anatomic shunt (Q_s/Q) from arterial oxygen tension during breathing of 100 per cent oxygen is given in Fig. 1

Cardiac output (Q) (VI) was estimated from the actually measured oxygen consumption (V_{O_2}) and the assumed value of 3.5 ml/100 ml blood for the arterial – mixed venous oxygen difference using Fick's formula

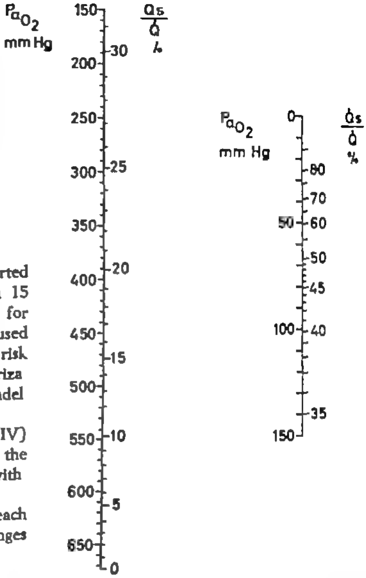
$$Q = (V_{O_2}/3.5)\quad 100\ (\text{ml}) \quad (5)$$

BLOOD COLLECTION (IV V VI)

Since capillary blood is not a reliable substitute for arterial blood during the neonatal period particularly with respect to P_{O_2} (Koch and Wendel, 1967 a) arterial blood had to be collected. In order to avoid disturbance of steady state conditions blood sampling had to be performed by means of an indwelling arterial catheter

Arterial blood was sampled from the descending aorta by means of a polyvinyl ca

FIG 1 Nomogram for calculating anatomic shunt ($\dot{Q}s/\dot{Q}$) from arterial oxygen tension (P_{aO_2}) during 100 per cent oxygen breathing
Left side nomogram for oxygen tensions above 150 mmHg right side nomogram for oxygen tensions below 150 mmHg (Nomograms are based on the assumptions of $P_{AO_2} = 673$ mmHg, arterio-venous O_2 difference = 3.5 ml/100 ml, O_2 cap = 23 ml/100 ml) (V)



theter (feeding tube French size 5) inserted in one of the umbilical arteries within 15 minutes after delivery and left in place for maximally 7 days With the technique used this procedure was considered free of risk and no complications caused by the catherization were observed (Koch and Wendel 1967 b)

Whenever cord blood was sampled (IV) the umbilical artery and subsequently the umbilical vein were directly punctured without clamping the cord

Blood samples between 1 and 5 ml each were collected in 5 ml heparinized syringes and immediately iced.

BLOOD ANALYSES (IV V VI)

Blood gas analyses and determination of pH were performed within 60 minutes after sampling, Pa_{O_2} and Pa_{CO_2} after oxygen breathing were determined immediately

pH was measured at 37 C with a thermostated microglass electrode The same standard phosphate buffer solution (Koch 1965) was used throughout the study

Carbon dioxide tension (Pa_{CO_2}) was determined with a Severinghaus type electrode (Severinghaus and Bradley 1959) and *oxygen tension* (Pa_{O_2}) with a Clark type microelectrode (Clark, 1956) with a polypropylene membrane During a part of the studies (VI) carbon dioxide tension was also measured by the microequilibration technique (Siggaard Andersen et al. 1960)

Standard bicarbonate and *total CO_2 content* were determined by the microequilibration technique or by use of the Siggaard Andersen s alignment nomogram (1963) The validity of this nomogram for neonatal blood was shown by determining the first dissociation coefficient of carbonic acid in umbilical venous blood, and comparing total CO_2 content determined directly by the manometric Van Slyke technique with the values obtained from the alignment nomogram (IV)

Oxygen saturation (S_{O_2}) and *hemoglobin concentration* (Hb) were measured spectro-

photometrically the *hematocrit* (Hct) was determined by microcapillary technique Oxygen *capacity* (O_2 cap) was derived from hemoglobin concentration assuming 1 g hemoglobin to combine with 1.34 ml O_2 STPD (IV)

Lactic acid concentration was determined *enzymatically* (IV) and *pyruvic acid* concentration by the method of Friedeman and Haugen (1943) as modified by Huckabee (1956)

Carbon monoxide content (VI) of arterial blood was determined in 0 1 ml samples by microtechnique (Linderholm, 1965)

GAS ANALYSES (VI)

Fractions of *oxygen carbon dioxide* and *nitrogen* in inspiratory and exspiratory gases were determined according to Scholander (1957) *Carbon monoxide* in the gas phase was measured with a hopcalite CO-meter (Linderholm and Sjöstrand 1956)

For the most important analytical procedures used in this series of studies methodological errors expressed as the standard error of a single determination (Sx) and the coefficient of variation (v) calculated from duplicate determinations are given in Table I

TABLE I.

RESULTS

THE ONSET OF BREATHING IN TERMS OF PULMONARY VENTILATION AND MECHANICS OF BREATHING (I)

Changes prior to the first breath

Among 10 cases in whom a record prior to the first breath was obtained in 3 instances inspiratory and in 5 expiratory volume changes amounting to 5—25 ml were recorded in general accompanied by slight changes in intraoesophageal pressure

First breaths

In 10 cases (Case No 71 excluded) where the first breath could be recorded this occurred between [illegible] and 55 seconds counted from the moment when the head was outside the vulva The volume displacement effected by the first breath ranged between 12 and 67 ml the maximal intraoesophageal pressure changes during inspiration ranged between −4 and −70 cm H_2O and during expiration between +5 and +70 cm H_2O The subsequent breaths had in general a similar pressure volume pattern but showed a tendency toward decreased magnitudes in both pressure and volume The total intrathoracic pressure swing during the first breath ranged from 40 to 100 cm H_2O

Residual volume

In 7 of 11 infants the end expiratory level of the first breath was between 4 and 30 ml higher than the inspiratory starting level and was mainly maintained at this higher level during the subsequent breaths This volume shift is consistent with the build up of a residual volume In two cases the end expiratory level was constant in two (Nos 48 and 66) it was by 7 and 9 ml respectively lower than the starting level. In these two infants some »expiratory» volume change had been recorded prior to the first breath which suggests that some volume gain may have occurred before recording was started.

Initial breathing pattern respiratory rate and 20 seconds ventilation

There were mainly 3 patterns of initial respiration 1) regular rhythmic respiration with a relatively high respiratory rate (>25/min) 2) regular periodic breathing and 3) breathing with irregular periodicity Accordingly respiratory rate showed large variations and the initial 20 seconds ventilation ranged between 78 and 790 ml

Mechanical factors

Pressure volume diagrams (respiratory loops) of the first breath and in general even the subsequent breaths had a more or less quadratic form indicating high pulmonary resistance and probably at least in most cases low lung compliance Variations in the magnitude of negative and positive pressures necessary and their relationship to each other were however large According to

TABLE II

Mechanics of breathing. Mean values (M) and standard deviation (SD) obtained at the age periods 2—35 minutes, 1—2.5 hours and 24 hours—7 days and statistical significance level (p) of mean differences (birth weight 3430 ± 400 g) (II)

Age group (range)		2—35 minutes M	SD	range			1—2.5 hours M	SD	range		n	1—8 days M	SD	range
Lung compliance, ml/cm H_2O	20	2 7	0 9	1 0—4 0	$p < 0\ 001$	15	3 9	0 9	3 0—6 4	$p < 0\ 001$	31	5 6	1.8	2 6—11 0
Pulm. resistance cm H_2O/l/sec	20	35	20	14—98	$p > 0\ 1$	15	27	14	7—48	$p > 0\ 5$	28	27	12	7—48
Insp. work, total, g cm	20	245	108	54—400	$p > 0\ 05$	15	183	95	60—400	$p > 0\ 8$	28	190	102	66—490
Insp. work, elastive part, %	20	68	14	39—87	$p > 0.7$	15	66	12	42—79	$p > 0\ 05$	28	60	11	42—81
Mean tidal volume (rebreathing) ml	20	[illegible]	7 4	15—44	$p > 0.3$	15	20	6.7	19—4	$p > 0\ 05$	31	34	8 0	20—48

the magnitude of inspiratory pulmonary resistance two rather distinct groups can be separated one with rather low and the other with higher resistance The group with the lower inspiratory pulmonary resistance appears to have a tendency towards higher compliance

Inspiratory work during the first breaths in relation to tidal volume is significantly higher than during quiet breathing, but of the same order as during crying in newborns at the age of some days

FURTHER DEVELOPMENT OF THE MECHANICAL PROPERTIES OF THE LUNG DURING THE FIRST WEEK OF LIFE (II)

As early as at the age of 2—3 minutes i. e after approximately 40—100 breaths the respiratory loops during quiet breathing are smaller and volume and pressure variations less Lung compliance increases and pulmonary resistance total inspiratory work and the part of inspiratory work done to overcome elastic forces decrease There is a fairly rectilinear relationship between compliance pulmonary resistance inspiratory work/V_T^2 respectively and age when plotted on a double logarithmic scale This means that changes proceed most rapidly in the very beginning of extrauterine life and only insignificant changes occur during the period between 24 hours and 8 days of age In eleven infants studied both at 24 hours and 7 days there were no statistically significant differences between the values obtained at the two ages (V_T D [8 days — 24 hours] = 1 ± 9 ml $p > 0\ 6$) lung compliance D = 0.9 ± 2.8 ml/cm H_2O $p > 0.3$ pulmonary resistance D = —2.6 ± 12 1 cm H_2O/l/sec, $p > 0.5$ total inspiratory work D = —10 4 ± 76 g cm, $p > 0\ 6$ elastive part of inspiratory work D —3.9 ± 13.5 % $p > 0.3$)

Mean values found at different age periods, namely 2—35 minutes 60—150 minutes and

mean value ± standard deviation.

RESULTS

THE ONSET OF BREATHING IN TERMS OF PULMONARY VENTILATION AND MECHANICS OF BREATHING (I)

Changes prior to the first breath

Among 10 cases in whom a record prior to the first breath was obtained in 3 instances inspiratory and in 5 expiratory volume changes amounting to 5—25 ml were recorded in general accompanied by slight changes in intraoesophageal pressure

First breaths

In 10 cases (Case No 71 excluded) where the first breath could be recorded this occurred between 6 and 55 seconds counted from the moment when the head was outside the vulva The volume displacement effected by the first breath ranged between 12 and 67 ml the maximal intraoesophageal pressure changes during inspiration ranged between -4 and -70 cm H_2O and during expiration between +5 and +70 cm H_2O The subsequent breaths had in general a similar pressure volume pattern but showed a tendency toward decreased magnitudes in both pressure and volume The total intrathoracic pressure swing during the first breath ranged from 40 to 100 cm H_2O

Residual volume

the magnitude of inspiratory pulmonary resistance, two rather distinct groups can be separated, one with rather low and the other with higher resistance. The group with the lower inspiratory pulmonary resistance appears to have a tendency towards higher compliance.

Inspiratory work during the first breaths in relation to tidal volume is significantly higher than during quiet breathing, but of the same order as during crying in newborns at the age of some days.

FURTHER DEVELOPMENT OF THE MECHANICAL PROPERTIES OF THE LUNG DURING THE FIRST WEEK OF LIFE (II)

As early as at the age of 2—3 minutes, i.e. after approximately 40—100 breaths, the respiratory loops during quiet breathing are smaller and volume and pressure variations less. Lung compliance increases and pulmonary resistance, total inspiratory work and the part of inspiratory work done to overcome elastic forces decrease. There is a fairly rectilinear relationship between compliance, pulmonary resistance, inspiratory work/V_T^2 respectively and age when plotted on a double logarithmic scale. This means that changes proceed most rapidly in the very beginning of extrauterine life and only insignificant changes occur during the period between 24 hours and 8 days of age. In eleven infants studied both at 24 hours and 7 days, there were no statistically significant differences between the values obtained at the two ages (V_T: D [8 days — 24 hours] = 1 ± 9 ml, $p > 0.6$); lung compliance: D = 0.9 ± 2.8 ml/cm H_2O, $p > 0.3$; pulmonary resistance: D = −2.6 ± 12.1 cm H_2O/l/sec, $p > 0.5$; total inspiratory work: D = −10.4 ± 76 g cm, $p > 0.6$; elastive part of inspiratory work: D −3.9 ± 13.5 %, $p > 0.3$).

Mean values found at different age periods, namely 2—35 minutes, 60—150 minutes and

mean value ± standard deviation.

24 hours — 7 days are given in Table II Lung compliance corrected for body size differences was 0 79 ± 0 07 1 15 ± 0.3 and 1 68 ± 0 6 ml/cmH_2O/kg birth weight respectively Only for lung compliance there was a statistically significant difference ($p < 0\,001$) between the means of these three age groups

FUNCTIONAL RESIDUAL CAPACITY (III)

The functional residual capacity shows a gradual increase between the age of 1—2 hours and 24 hours In 6 infants who were followed from 1—2 hours up to 24 hours of life this increase was observed in each case and averaged 14 ± 8 ml (from 91 to 105 ml $p < 0\,01$)

No significant change seems to occur between 24 hours and several days of age. FRC averaged 93 ± 18 5 ml (n = 16 range 69—135 ml) at 24 hours and 82 ± 21 ml (n = 9 range 54—103 ml) at the age 6—12 days without a statistically significant difference ($0\,05 < p < 0\,1$) between the means.

Already during the first day of life, FRC and compliance (C) are highly correlated FRC (ml) = 10 1 C (ml/cm H_2O) + 56 4 (n = 17 SEE (y) = 16 1 r = 0 77 $p < 0\,01$) The specific compliance (compliance/FRC) during the first day of life is 0 042 ± 0 01 (n = 17) thus approaching already during the first day relations seen later in life

BLOOD GASES AND ACID-BASE BALANCE DURING THE FIRST WEEK (IV)

There is hypoxemia hypercapnea and both respiratory and non respiratory (metabolic) acidosis at birth as reflected by umbilical

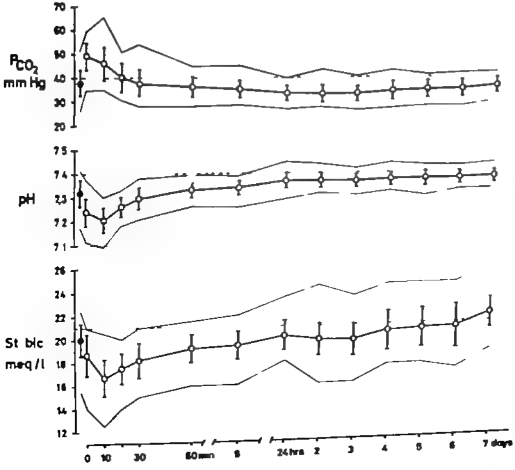

FIG 2. Mean, standard deviation and range of arterial carbon dioxide tension, pH and standard bicarbonate at different ages during the first week of life (IV) Open circles (o) values in blood of th descendi g aorta (at time 0 n umbilical cord ar tery) filled circles ( ) at time 0 values in blood f the umbilical cord vein.

arterial blood (Fig. 2) with accumulation of lactic and pyruvic acid (IV). Acidosis and lactic acid concentration (Fig. 6) further increase during the first minutes following birth, but recede rapidly and steadily during the subsequent minutes and hours. Respiratory acidosis (hypercapnea) is abolished within 30 to 60 minutes after delivery while pH exceeds 7.35 only after 24 hours of life at the same time lactate and pyruvate values have approached adult resting values while P_{CO_2} is about 33 mm Hg. The adjustment of pH to normal adult values thus occurs in spite of persisting hypobasemia which is apparently counterbalanced by hyperventilation. Hypobasemia recedes significantly ($p < 0.001$) during the rest of the first week of life and standard bicarbonate reaches the lower limit of the normal adult range by the 7th day of life. This rise in standard bicarbonate is paralleled by a corresponding increase ($p < 0.001$) in P_{CO_2} from the age of 24—72 hours untill 7 days (IV Fig 2). There are no significant differences in lactic acid concentration between 24 hours and 7 days (1.0 ± 0.15 and 0.9 ± 0.25 meq/l respectively $p > 0.2$, IV).

Normal arterial saturation is on the average achieved by about 5 hours of life by which time P_{aO_2} is about 73 mm Hg without any further significant change during the remainder of the first week of life (Fig. 3).

Oxygen capacity and hematocrit decrease slightly from the age of 5 and 24 hours respectively (Fig 3).

The changes occurring in pH, P_{aCO_2}, standard bicarbonate P_{aO_2} and S_{aO_2} are significantly correlated to age and can be expressed as logarithmic functions of age (Table III) thus permitting prediction of normal values.

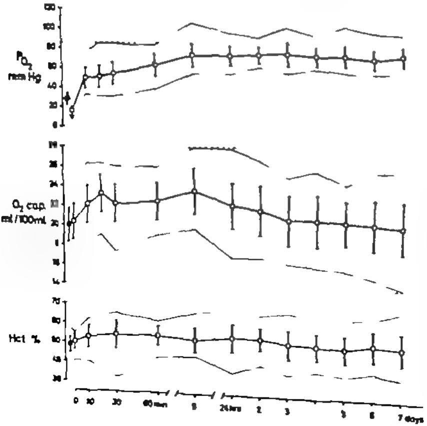

FIG 3 Mean, standard deviation and range of arterial oxygen tension during air breathing, and of oxygen capacity and hematocrit in arterial blood at different ages during the first week of lif (IV). Symbols as in Fig 2.

24 hours — 7 days are given in Table II Lung compliance corrected for body size differences was 0 79 ± 0 07 1 15 ± 0 3 and 1 68 ± 0 6 ml/cmH_2O/kg birth weight respectively Only for lung compliance there was a statistically significant difference ($p < 0\,001$) between the means of these three age groups

FUNCTIONAL RESIDUAL CAPACITY (III)

The functional residual capacity shows a *gradual increase* between the age of 1—2 hours and 24 hours In 6 infants who were followed from 1—2 hours up to 24 hours of life this increase was observed in each case and averaged 14 ± 8 ml (from 91 to 105 ml $p < 0\,01$)

No significant change seems to occur between 24 hours and several days of age FRC averaged 93 ± 18.5 ml (n = 16 range 69—135 ml) at 24 hours and 82 ± 21 ml (n = 9 range 54—103 ml) at the age 6—12 days without a statistically significant difference ($0\,05 < p < 0\,1$) between the means

Already during the first day of life, FRC and compliance (C) are highly correlated FRC (ml) = 10 1 C (ml/cm H_2O) + 56 4 (n = 17 SEE (y) = 16 1 r = 0 77 $p < 0\,01$) The specific compliance (compliance/FRC) during the first day of life is 0 042 ± 0 01 (n = 17) thus approaching already during the first day relations seen later in life

BLOOD GASES AND ACID-BASE BALANCE DURING THE FIRST WEEK (IV)

There is hypoxemia hypercapnea and both respiratory and non respiratory (metabolic) acidosis at birth as reflected by umbilical

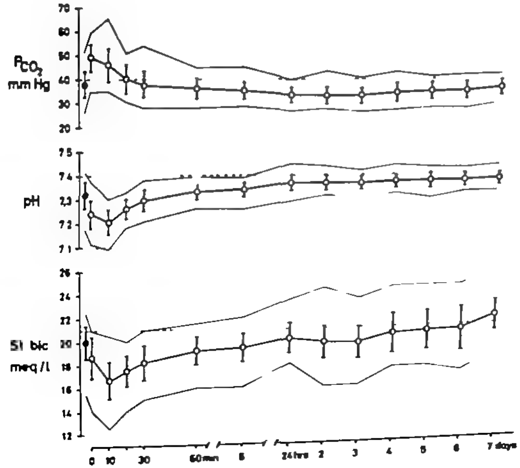

FIG 2. Mean, standard deviation and range of arterial carbon dioxide tension, pH and standard bicarbonate at different ages during the first week of life (IV) Open circles (o) values in blood of the descending aorta (at time 0 in umbilical cord artery) filled circles ( ) at time 0 values in blood of the umbilical cord vein.

at the age of 35 minutes averaging 356 mm Hg at the age of 5 hours to 7 days it averaged between 95 and 141 mm Hg.

Venous admixture due to anatomic shunt averaged 24 per cent of right ventricular output at the age of 35 minutes but decreased to an average between 7.6—10.9 per cent during the period 5 hours to 7 days, the lowest values being found at the age of 2 and 3 days (Fig 4)

STEADY STATE PULMONARY VENTILATION AND DIFFUSING CAPACITY (VI)

Obstetrical data and individual data for most of the variables studied in connection with determination of D_{LCO} at 24 hours and 7 days of life are given in the Appendix Tables 1 2, 3 Table IV shows the mean values obtained at 24 hours and 7 days respectively as well as the mean differences.

Minute volume ($\dot{V}_E$) oxygen consumption ($\dot{V}_{O_2}$) carbon dioxide elimination ($\dot{V}_{CO_2}$) and alveolar ventilation ($\dot{V}_A$) are statistically significantly correlated to body size This held also for tidal volume (V_T) when only cases with a regular breathing pattern were selectected (cf VI)

Between 24 hours and 7 days of age there was a slight decrease ($p < 0.01$) of the respiratory rate and the alveolar ventilation equivalent for CO_2 ($\dot{V}_A/\dot{V}_{CO_2}$) and increase ($p < 0.001$) of the respiratory exchange ratio (R) Minute volume ($\dot{V}_E$) decreased and heart rate increased slightly ($p < 0.05$) Changes in tidal volume (V_T) oxygen consumption ($\dot{V}_{O_2}$) ventilation equivalent for O_2 ($\dot{V}_E/\dot{V}_{O_2}$) carbon dioxide elimination ($\dot{V}_{CO_2}$) alveolar ventilation ($\dot{V}_A$) and physiological dead space (V_D) were slight and statistically not significant.

Both the physiological dead space/tidal volume ratio (V_D/V_T) and the diffusing capacity (D_{LCO}) decreased slightly from 24 hours to 7 days ($p < 0.05$)

The ratio V_D/V_T D_{LCO} in relation to $\dot{V}_A$, $\dot{V}_{O_2}$ and body surfac area (BSA) and the alveolar – mean pulmonary capillary oxygen tension difference ($P_{AO_2} - P_{cO_2}$) correspond to standard adult values

A-a O_2 DIFFERENCE AND TOTAL VENOUS ADMIXTURE (VI)

During air breathing Pa_{O_2} was on the average 72 and 74 mm Hg at 24 hours and 7 days of life and the $P_{AO_2} - Pa_{O_2}$ difference 31 and 30 mmHg corresponding to a total venous admixture during air breathing of 20.9 ± 6 and 18.4 ± 5.9 per cent of right ventricular output respectively ($p < 0.05$)

CARDIAC OUTPUT AND OVERALL VENTILATION/PERFUSION RATIO (VI)

Calculated from the assumed value of 3.5 ml/100 ml for the arterial - mixed venous oxygen difference (cf VI) and measured oxygen uptake cardiac output averaged 699 ± 112 ml and 646 ± 101 ml at 24 hours and 7 days respectively This slight change parallels the decrease of $\dot{V}_{O_2}$ from 24 hours to 7 days.

The overall ventilation/perfusion ratio ($\dot{V}_A/\dot{Q}$) estimated from these values for $\dot{Q}$ and the corresponding measured values for $\dot{V}_A$ averaged 0.63 and 0.66 at 24 hours and 7 days ($0.05 < p < 0.1$)

TABLE III.

Regression equations for pH P_{aCO_2} standard bicarbonate oxygen saturation and P_{O_2} during air breathing, and for P_{O_2} alveolar-arterial oxygen difference and anatomic shunt during oxygen ($F_{IO_2} = 1$) breathing as logarithmic functions of age (independent variable)

VENOUS ADMIXTURE DUE TO TRUE ANATOMIC SHUNT DURING THE FIRST WEEK OF LIFE (V)

P_{aO_2} during oxygen breathing averaged 309 mm Hg with a wide range (60—540 mm Hg) at the age of 55 minutes but showed a considerably higher mean level between 527—589 mm Hg, from 5 hours to 7 days of age (Fig 4)

The P_{aO_2} of 60 mmHg was the only value below 100 mmHg observed in this series during oxygen breathing. In spite of this unusually low value the infant appeared normal judging from the clinical condition and from pH, P_{aCO_2} bicarbonate and lactate values. P_{aO_2} during air breathing was 40 mmHg at 60 minutes and 55 mmHg at 5 hours of age at which time P_{aO_2} during oxygen breathing attained 497 mmHg

Correspondingly the average alveolar-arterial oxygen tension difference was highest

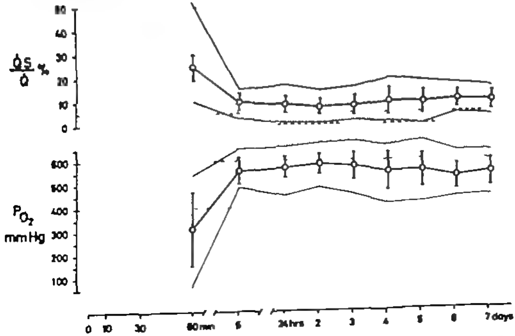

FIG 4 Mean, standard deviation and range of arterial oxygen tension during oxygen breathing and calculated anatomi shunt at different ages during the first week of life (V) Symbols as in Fig. 2

at the age of 55 minutes averaging 356 mm Hg at the age of 5 hours to 7 days it averaged between 95 and 141 mm Hg.

Venous admixture due to anatomic shunt averaged 24 per cent of right ventricular output at the age of 55 minutes but decreased to an average between 7.6—10.9 per cent during the period 5 hours to 7 days the lowest values being found at the age of 2 and 3 days (Fig. 4)

STEADY STATE PULMONARY VENTILATION AND DIFFUSING CAPACITY (VI)

Obstetrical data and individual data for most of the variables studied in connection with determination of D_{LCO} at 24 hours and 7 days of life are given in the Appendix, Tables 1 2, 3 Table IV shows the mean values obtained at 24 hours and 7 days respectively as well as the mean differences

Minute volume (V_E) oxygen consumption (V_{O_2}) carbon dioxide elimination (V_{CO_2}) and alveolar ventilation (V_A) are statistically significantly correlated to body size This held also for tidal volume (V_T) when only cases with a regular breathing pattern were selectected (cf VI)

Between 24 hours and 7 days of age there was a slight decrease ($p < 0.01$) of the respiratory rate and the alveolar ventilation equivalent for CO_2 (V_A/V_{CO_2}) and increase ($p < 0.001$) of the respiratory exchange ratio (R) Minute volume (V_E) decreased and heart rate increased slightly ($p < 0.05$) Changes in tidal volume (V_T) oxygen consumption (V_{O_2}) ventilation equivalent for O_2 (V_E/V_{O_2}) carbon dioxide elimination (V_{CO_2}) alveolar ventilation (V_A) and physiological dead space (V_D) were slight and statistically not significant.

Both the physiological dead space/tidal volume ratio (V_D/V_T) and the diffusing capacity (D_{LCO}) decreased slightly from 24 hours to 7 days ($p < 0.05$)

The ratio V_D/V_T D_{LCO} in relation to V_A V_{O_2} and body surfac area (BSA) and the alveolar – mean pulmonary capillary oxygen tension difference ($P_{AO_2} - P_{cO_2}$) correspond to standard adult values.

A-a O_2 DIFFERENCE AND TOTAL VENOUS ADMIXTURE (VI)

During air breathing Pa_{O_2} was on the average 72 and 74 mm Hg at 24 hours and 7 days of life and the $P_{AO_2} - Pa_{O_2}$ difference 31 and 30 mmHg corresponding to a total venous admixture during air breathing of 20.9 ± 6 and 18.4 ± 5.9 per cent of right ventricular output respectively ($p < 0.05$)

CARDIAC OUTPUT AND OVERALL VENTILATION/PERFUSION RATIO (VI)

Calculated from the assumed value of 3.5 ml/100 ml for the arterial – mixed venous oxygen difference (cf VI) and measured oxygen uptake cardiac output averaged 699 ± 112 ml and 646 ± 101 ml at 24 hours and 7 days respectively This slight change parallels the decrease of V_{O_2} from 24 hours to 7 days.

The overall ventilation/perfusion ratio (V_A/Q) estimated from these values for Q and the corresponding measured values for V_A averaged 0.63 and 0.66 at 24 hours and 7 days ($0.05 < p < 0.1$)

DISCUSSION

METHODS

The small size and the lack of cooperation of the subject to be studied make pulmonary function investigation in the newborn period difficult and limit its possibilities The present series of studies as well as those of others (Cook et al 1955 Stahlman 1957 Nelson et al 1962 Strang and McGrath 1962 Prod'hom et al 1964 and others) however have demonstrated that suitable methods can be developed or adapted permitting investigation of the main mechanisms in respiratory function even in the youngest age group

If in the present study (VI) in spite of the biological changes occurring, the serial examinations at 24 hours and 7 days of age (Table IV) are considered as duplicate determinations then it appears that for most of the variables of particular importance for respiratory gas exchange including alveolar ventilation and pulmonary diffusing capacity a methodological reliability of the same order as in corresponding investigations in resting adults can be achieved

ONSET OF RESPIRATION AND INITIAL RESPIRATORY ADJUSTMENT

Since at initiation of extrauterine life the fetus emerges from a watery environment into air removal of lung liquid filling the alveolar spaces and upper airways is a prerequisite for successful aeration and gas exchange. In the mature fetal lamb the liquid contained in the lungs at term is in the order of 40—80 ml which appears to be similar to that of the functional residual capacity of gas after initiation of breathing (Howatt et al. 1965) Similar figures ought to apply to the human fetus the functional residual capacity has actually been shown to be of the same magnitude (III Strang and McGrath 1962 Prod'hom et al 1964 Chu et al 1964) Provided there is low surface tension in the lung after introduction of air the resting position of the lungs should thus be the same wether they contain liquid or air (Strang, 1967) Lung liquid can be drained probably mostly from the upper airways, in considerable amounts during the delivery process particularly during vaginal vertex delivery (Karlberg et al. 1962) leading to a more or less extensive air filling of the upper air passages prior to the first breath (III Lind et al 1964) Although water in the alveolar spaces themselves may be absorbed mainly into the pulmonary circulation (Potter 1953) there is at least in the newborn lamb also evidence for removal of lung liquid through lymphatic channels in the pulmonary interstitial tissue (Boston et al 1965) According to Strang (1967) the increase in lymph flow above the fetal level in the first two hours of ventilation could account for the removal of 30 per cent of the water and all the protein in the lung liquid.

The establishment of air liquid interfaces during the first breath generates surface ten

sions the magnitude of which determines further aeration. The high negatives pressures and high lung resistances regularly encountered during the first and often even the following breaths (I) reflect probably mainly cohesive surface tensions According to Laplace's law surface tensions must be expected to diminish with increasing diameter of the air bubble in the alveoli partly filled with air and partly with liquid, i.e. with progressive removal of liquid and its replacement by air It actually seems that the air filled part of the alveolus takes the shape of an optimally-curved spherical bubble (Plank, 1967) Characteristically in most of the infants in which the first breath showed a residual volume the subsequent inspirations proceeded more easily judging from the slope of the inspiratory pressure volume curve

During deflation, surface tension can be expected to exert a retractive pressure and can thus not account for the high positive pressures observed during expiration and the resulting square form of the respiratory loop. These are probably due to upper airway obstruction during the expiratory phase secondary to pharyngo-laryngeal closure (I)

With respect to the inspiratory part similar pressure volume curves as those obtained during the first breath and sometimes the following breaths have been observed in fetal lungs of the lamb when inflated with positive pressure (Strang, 1967) While the pressure magnitude and the slope of the inflation loop does not seem to differ significantly between mature and immature fetal lungs, during deflation, the latter retains less air at decreasing inflating pressures than the former and tends towards loosing all air when pressure returns to zero A similar displacement of the deflation curve towards decreased volume has been found in lung preparations from infants succumbing to the Idiopathic Respiratory Distress Syndrome (IRDS) when compared with the lungs of newborn infants dieing from other than pulmonary causes and was correlated to differences in the surface activity of lung extracts (Gribetz et al 1959 Gruenwald et al., 1962) The low air-retaining capacity of the immature in relation to the mature lamb lung has also been ascribed to surface activity differences namely higher surface tension in the alveoli of the immature lung. By generating higher lung retractive forces high surface tension would not only prompt alveolar collapse but might even tend to suck back liquid into the alveolus (Boston et al. 1965 Strang, 1967)

In accordance with these observations in mature fetal lamb lungs in most of the infants in whom the first breaths could be recorded a residual volume was established during the first or more seldom, during one of the following breaths as shown from a smaller deflation in relation to inflation volume In some cases however such a residual volume was not observed this could signify 1) that replacement of lung liquid by air occurs at a slower rate or 2) that normal liquid replacement persists after expiration but the resting position of the lungs changes tending to diminish thoracic volume or 3) that some aeration has occurred before the first breaths. Cineradiological examination of the onset of respiration (III) shows in agreement with the different types of initation of respiration as shown by the analysis of the volume pressure relationship (I) that initial aeration can proceed more or less easily and rapidly but complete disappearance of air from the lung fields after the first expiration was not observed. While aeration of the upper airways may occur prior to the first breath (III Lind et al. 1964) there is no evidence that significant aeration of alveolar spaces may occur at this stage

While it thus appears that even in the normal infant variation in the mechanical properties at birth is large no definite conclusions as to the causes of this variation can be drawn from the present study (I) It is tempting to speculate that there may

DISCUSSION

METHODS

The small size and the lack of cooperation of the subject to be studied make pulmonary function investigation in the newborn period difficult and limit its possibilities The present series of studies as well as those of others (Cook et al 1955 Stahlman, 1957 Nelson et al 1962 Strang and McGrath 1962 Prod hom et al 1964 and others) however have demonstrated that suitable methods can be developed or adapted permitting inves tigation of the main mechanisms in respira tory function even in the youngest age group

If in the present study (VI) in spite of the biological changes occurring, the serial examinations at 24 hours and 7 days of age (Table IV) are considered as duplicate de terminations then it appears that for most of the variables of particular importance for res piratory gas exchange including alveolar ven tilation and pulmonary diffusing capacity a methodological reliability of the same order as in corresponding investigations in resting adults can be achieved

ONSET OF RESPIRATION AND INITIAL RESPIRATORY ADJUSTMENT

Since at initiation of extrauterine life the fetus emerges from a watery environment into air removal of lung liquid filling the alveolar spaces and upper airways is a pre-requisite for successful aeration and gas ex change. In the mature fetal lamb the liquid contained in the lungs at term is in the order of 40—80 ml which appears to be similar to that of the functional residual capacity of gas after initiation of breathing (Howatt et al 1965) Similar figures ought to apply to the human fetus the functional residual capacity has actually been shown to be of the same magnitude (III Strang and McGrath 1962 Prod'hom et al. 1964 Chu et al 1964) Provided there is low surface tension in the lung after introduction of air the resting position of the lungs should thus be the same wether they contain liquid or air (Strang, 1967) Lung liquid can be drain ed probably mostly from the upper airways in considerable amounts during the delivery process particularly during vaginal vertex delivery (Karlberg et al. 1962) leading to a more or less extensive air filling of the upper air passages prior to the first breath (III Lind et al 1964) Although water in the alveolar spaces themselves may be ab-sorbed mainly into the pulmonary circulation (Potter 1953) there is at least in the newborn lamb, also evidence for removal of lung liquid through lymphatic channels in the pulmonary interstitial tissue (Boston et al 1965) Ac cording to Strang (1967) the increase in lymph flow above the fetal level in the first two hours of ventilation could account for the removal of 30 per cent of the water and all the protein in the lung liquid.

The establishment of air liquid interfaces during the first breath generates surface ten

sions, the magnitude of which determines further aeration. The high negative pressures and high lung resistances regularly encountered during the first and often even the following breaths (I) reflect probably mainly cohesive surface tensions. According to Laplace's law surface tensions must be expected to diminish with increasing diameter of the air bubble in the alveoli partly filled with air and partly with liquid, i.e. with progressive removal of liquid and its replacement by air. It actually seems that the air filled part of the alveolus takes the shape of an optimally-curved spherical bubble (Plank, 1967). Characteristically in most of the infants in which the first breath showed a residual volume the subsequent inspirations proceeded more easily judging from the slope of the inspiratory pressure volume curve.

During deflation, surface tension can be expected to exert a retractive pressure and can thus not account for the high positive pressures observed during expiration and the resulting square form of the respiratory loop. These are probably due to upper airway obstruction during the expiratory phase secondary to pharyngo-laryngeal closure (I).

With respect to the inspiratory part similar pressure volume curves as those obtained during the first breath and sometimes the following breaths have been observed in fetal lungs of the lamb when inflated with positive pressure (Strang, 1967). While the pressure magnitude and the slope of the inflation loop does not seem to differ significantly between mature and immature fetal lungs during deflation, the latter retains less air at decreasing inflating pressures than the former and tends towards loosing all air when pressure returns to zero. A similar displacement of the deflation curve towards decreased volume has been found in lung preparations from infants succumbing to the Idiopathic Respiratory Distress Syndrome (IRDS) when compared with the lungs of newborn infants dieing from other than pulmonary causes and was correlated to differences in the surface activity of lung extracts (Gribetz et al., 1959 Gruenwald et al., 1962). The low air-retaining capacity of the immature in relation to the mature lamb lung has also been ascribed to surface activity differences, namely higher surface tension in the alveoli of the immature lung. By generating higher lung retractive forces high surface tension would not only prompt alveolar collapse but might even tend to suck back liquid into the alveolus (Boston et al., 1965 Strang, 1967).

In accordance with these observations in mature fetal lamb lungs in most of the infants in whom the first breaths could be recorded, a residual volume was established during the first or more seldom, during one of the following breaths as shown from a smaller deflation in relation to inflation volume. In some cases however such a residual volume was not observed this could signify 1) that replacement of lung liquid by air occurs at a slower rate or 2) that normal liquid replacement persists after expiration but the resting position of the lungs changes tending to diminish thoracic volume or 3) that some aeration has occurred before the first breaths. Cineradiological examination of the onset of respiration (III) shows in agreement with the different types of initation of respiration as shown by the analysis of the volume pressure relationship (I) that initial aeration can proceed more or less easily and rapidly but complete disappearance of air from the lung fields after the first expiration was not observed. While aeration of the upper airways may occur prior to the first breath (III, Lind et al. 1964) there is no evidence that significant aeration of alveolar spaces may occur at this stage.

While it thus appears that even in the normal infant variation in the mechanical properties at birth is large no definite conclusions as to the causes of this variation can be drawn from the present study (I). It is tempting to speculate that there may

be interindividual differences in lipoproteine surface activity and thus in surface tension even among normal term infants

The great interindividual variability with respect to breathing pattern respiratory rate and minute volume as well as to the mechanical properties persists during the first minutes already at 3—10 minutes however a striking similarity of the respiratory loops approaching the pattern seen after some hours and days of life (II) demonstrates the rapidity with which lung structures accomodate for aeration.

As reflected by arterial blood gases (P_{aO_2} P_{aCO_2}) the degree of alveolar aeration and of mechanical adjustment allows very rapidly for effective pulmonary ventilation and gas exchange At 5 to 10 minutes after delivery P_{aCO_2} has already decreased to 46 ± 7 mm Hg and P_{aO_2} in the descending aorta has reached 50 ± 10 mm Hg Analysis focused on the very first minutes of postnatal development have shown that from about one to two minutes adjustment is effective enough to allow for increasing oxygenation and CO_2 elimination as judged from arterial blood gases (Engstrom et al 1966)

By 30—60 minutes of age lung function appears to be firmly established as judged from functional residual capacity mechanical properties of the lung and gas exchange as revealed by arterial blood gases Respiratory acidosis is on the average abolished at this time ($P_{aCO_2} = 38 \pm 6$ mm Hg at 30 minutes and 36 ± 4 mm Hg at 60 minutes of life) while a relative hypoxemia both in terms of oxygen saturation of the hemoglobin and oxygen tension in descending aortic blood persists The relatively low P_{aO_2} compared to normal adult standards at this age has been shown to correspond to an increased alveolar arterial P_{O_2} difference (Prod'hom et al 1964) The low P_{aO_2} in spite of rather normal effective alveolar oxygen tension (P_{AO_2}) at this age appears to be for the most part due to anatomic R L shunt, which probably occurs mainly through normal fetal pathways (foramen ovale and ductus arteriosus) and to a minor degree to ventilation/perfusion inequality i e low ventilation/perfusion ratio According to Prod'hom et al (1964) roughly 2/3 of total venous admixture is due to anatomic shunt at the age of about 90 minutes Estimations based on own figures of P_{aO_2} in the descending aorta during air and oxygen breathing (V) suggest a similar figure namely about 80 per cent of total venous admixture to be caused by anatomic shunt at the age of 55 minutes

FURTHER DEVELOPMENT OF PULMONARY MECHANICS AND LUNG VOLUME

Within a few minutes after delivery respiratory loops during quiet breathing have approached the shape seen later during the neonatal period. At this age (range 2—35 minutes) lung compliance is 2.7 ± 0.9 ml/cm H_2O and increases to 3.9 ± 0.9 ml/cm H_2O at 1—2.5 hours and 5.6 ± 1.8 ml/cm H_2O at the age of 1—8 days (Table II) This increase is statistically highly significant. On the other hand, there is no statistically significant difference between the compliance measured at 24 hours and 8 days respectively The compliance values found after some hours of life (II III) are in good agreement with the values obtained by means of an air filled system for measurement of oesophageal pressure (Swyer et al 1960 Chu et al, 1964) and different techniques for measuring volume changes (cf Polgar 1967) The trend of changes in compliance occurring during the first day of life has been confirmed by Drorbaugh et al. (1963) and Chu et al (1964) On the other hand respiratory work is significantly higher than the values reported by Cook et al. (1957) and Swyer et al (1960) This is apparently due to the significantly bigger tidal volumes obtained with the reverse plethysmograph technique following rebreathing Our values concerning

respiratory work are thus not representative for basal standards but rather to be considered as an index for the changes occurring. On the other hand, the elastive part of respiratory work corresponds fairly well with the values reported by the above mentioned authors.

FRC measured at 0.5—2 hours 24 hours and 3—12 days of age fall into the same range of magnitude, and there is no statistically significant difference between FRC values obtained at an age of 24 hours and 6—12 days respectively ($p > 0.1$) If serial measurements in the same individuals between 1—2 hours and 24 hours of age are compared, there is, however a slight, yet statistically significant increase ($p < 0.01$) suggesting that the increase in compliance is parallelled by a similar yet proportionally smaller increase in FRC As later in life, FRC and compliance are highly correlated ($r = 0.77$) and specific compliance at the age 1—24 hours is on the average 0.042 ± 0.01 If however measurements at 1—2 and at 24 hours are treated separately the specific compliance is shown to increase significantly ($p < 0.01$) from 0.036 ± 0.008 to 0.05 ± 0.01 indicating that after the rapid accomodation occurring during the first minutes true changes in the elastic properties of the neonatal lung continue. A similar increase of specific compliance during the first hours of life has been noted by Chu et al. (1964) using the plethysmographic method (DuBois et al., 1956) for determination of FRC but not after 24 hours of life They enumerate the following possible causes for this initial increase (1) alterations in the elastic elements following repeated stretching, (2) loss of fluid from the lung during the first hours of postnatal life (3) changes in the alveolar surface-active lining or (4) increase with age in the number of alveoli participating in respiration. Changes in elastic properties due to loss of interstitial fluid seems so far the most realistic explanation since it is actually based on experimental evidence of decreasing lung weight in relation to body weight during the first 5 hours (Boston et al. 1965)

The compliance/FRC ratio of 0.055 ± 0.01 found by Chu et al. (1964) after 24 hours (1—7 days) agrees well with that found in the present study using the closed-circuit method for determination of FRC at 24 hours of age (III) as well as with adult standards. This suggests a striking similarity in the elastic properties of the mechanically adapted neonatal lung with that of the normal adult.

The FRC values found in the present study (III) are intermediate between those obtained by identical technique in a group of very early (29.3 ± 2.0 ml/kg) and very late (21.6 ± 1.4 ml/kg) clamped infants less than 6 hours of age (Oh et al., 1967) There is a good general agreement between the FRC measured with the He-method (26.5 ± 5.7 ml/kg birth weight III) the plethysmographic technique (29 ± 7.0 ml/kg Klaus et al., 1960 27.8 ml/kg Klaus et al. 1962 33.8 ± 7.3 ml/kg Auld et al., 1963) and the open-circuit nitrogen-washout method (31.3 ± 11.3 ml/kg Nelson et al 1963 a) in infants over 1 hour of age

When measuring lung volume concurrently with the nitrogen washout and the plethysmographic technique in the same individual Nelson et al. (1963 a) found however significantly higher values in 10 out of 22 infants with the plethysmographic method. They concluded, since the N_2 and the He-method measure the ventilated portion of the thoracic gas volume i. e. true FRC and the plethysmographic technique total thoracic gas volume that some healthy infants may have significant amounts of trapped air i. e. airway obstruction. This is a surprising finding in view of the rather even gas *distribution* shown in the newborn infant (Tooley et al. 1960 Strang and McGrath, 1962 Nelson et al., 1962 b)

While lung compliance shows a steady increase during the first 24 hours of life pulmonary resistance appears to be mainly unchanged after the age of 1—2 hours (Table II) averaging 27 cm H_2O/1/sec. At 2—35 minutes of life pulmonary resistance averaged 35 ± 20 cm H_2O/1/sec, the difference between this value and the value found later is however statistically not significant The values obtained after 1—2 hours of life are in good agreement with those obtained at corresponding ages by using pneumotachygraph flow recording (Swyer et al 1960 26 cm H_2O/1/sec Polgar and String, 1966 34 cm H_2O/1/sec) or calculation of flow rate from volume recording by means of a body plethysmograph (Cook et al 1957 29 cm H_2O/1/sec

Recently Polgar and collaborators succeeded in measuring even the subdivisions of pulmonary resistance airway resistance and lung tissue resistance in the newborn infant They determined airway resistance by means of the total body plethysmograph technique (DuBois et al 1956) and lung tissue resistance by the method of Marshall and DuBois (1956) substracting the airway resistance measured plethysmographically from the pulmonary resistance determined by directly plotting the resistive component of intraoesophageal pressure against airflow on an x y oscillograph (Polgar and String, 1966) By substracting total pulmonary resistance measured when breathing through a plastic oral airway of known resistance from the pulmonary resistance measured when breathing through the nose even nasal resistance to breathing could be estimated (Polgar and Kong, 1965) this latter was found to be 12.1 ± 5.5 cm H_2O/1/sec ($n = 5$) or about 42 per cent of the total airway resistance against about 63 per cent in adults However total pulmonary resistance in this series was higher (47.5 cm H_2O/1/sec) than values reported by other investigators When measured concurrently total pulmonary resistance was $34\ 1 \pm 8.9$ cm H_2O/1/sec and oral breathi airway resistance $25\ 4 \pm 6\ 4$ cm H_2O/1/s yielding an average lung tissue resistance $8\ 7 \pm 6$ cm H_2O/1/sec (Polgar and Strin 1966) this corresponds to approximately per cent of mean pulmonary resistance co rected for nasal resistance Though the err involved in this type of study in the newbo infant is larger than in the adult, these resul should indicate that total mean opposing r sistive forces in relation to minute ventilatio are lower in the newborn infant than in th adult (Polgar 1967) This should mainly b due to lower nasal resistance while oral air way resistance is similar and tissue resistanc somewhat higher in the newborn infant.

LATE ADJUSTMENT OF INTRAPULMONAR GAS EXCHANGE

After the rapid initial adaptative processe only minor changes occur during the remainder of the first week of life

During the subsequent hours of extrauterine life arterial oxygen saturation and oxygen tension continue to rise attaining by five hours of age 96 ± 3 per cent and 74 ± 1 mm Hg respectively During oxygen breathing, P_{aO_2} rises to 555 ± 56 mm Hg corresponding to an alveolar arterial P_{O_2} difference of 124 ± 54 mm Hg and an anatomic shunt of $9\ 8 \pm 3\ 9$ per cent of cardiac output. As discussed above these changes coincide with an important rise in lung compliance and probably some adjustment in FRC In spite of further small adjustments in the lung s mechanical properties oxygenation of arterial blood does not undergo any further changes of significance and anatomic shunt appears to be mainly unchanged with however a minimum value at 2 days of age ($7\ 6 \pm 3\ 1$ per cent) Thus even after one week s acclimatization to extrauterine existence the lung of the newborn infant has not yet attained the same efficiency for oxy

genation of arterial blood as that of the normal adult.

Theoretically decreased arterial oxygen tension can be caused either by alveolar hypoventilation or by mechanisms increasing the alveolar-arterial oxygen tension difference. Three factors may contribute to the latter (VI): 1) The *diffusion component* which may give rise to a $P_{AO_2} - P_{cO_2}$ difference in the presence of impaired diffusion, but in the normal subject only under conditions of hypoxic ambient air; 2) the *distribution component* including both alveoli receiving an excess of perfusion (low ventilation/perfusion ratio) and those receiving an excess of ventilation (high ventilation/perfusion ratio, i.e. large "alveolar" dead space) and 3) the *shunt component* due to anatomic shunt, i.e. shunting of venous blood into the post pulmonary circulation thus establishing a $P_{cO_2} - P_{aO_2}$ difference.

Alveolar oxygen and carbon dioxide tensions (VI) exclude alveolar hypoventilation at least from the age of 24 hours but similar alveolar gas tensions have been reported already at the age of 4 hours (Prod'hom et al., 1964) and are, at least in the normal infant, probably present even earlier as judged from arterial P_{CO_2} (IV).

In view of the magnitude of D_{LCO} and the low $P_{AO_2} - P_{cO_2}$ difference observed in the present study the diffusion component does not appear to contribute substantially to the $P_{AO_2} - P_{aO_2}$ difference at least during breathing of air and hyperoxic inspiratory gases.

Thus the alveolar-arterial P_{O_2} difference of 31 and 30 mm Hg during air breathing at 24 hours and 7 days, corresponding to a total venous admixture of on the average 20.9 and 18.4 per cent of the cardiac output (D = 2.5, $p < 0.05$) should be due to the effect of shunt and distribution component.

Since anatomic shunt determined during oxygen breathing was found to be 9.3 ± 3.5 and 9.7 ± 4.3 per cent of cardiac output respectively, it should account for approximately 43 and 59 per cent of total venous admixture at the age of 24 hours and 7 days respectively if one assumes that oxygen breathing does not change significantly neither blood flow through shunt channels nor the arterial-mixed venous O_2 difference (cf. V).

These results are conflicting with those from earlier reports (Nelson et al., 1963 b; Prod'hom et al., 1964) concerning mainly slightly premature infants delivered by caesarean section, in which venous admixture at least after 4 hours of age was considered to be mainly due to true anatomic shunt. The main causes for this discrepancy appear to be methodological differences in measuring P_{O_2} in blood with high oxygen tensions and the difference in gestational age of the infants studied and the type of their delivery (V).

As indicated by the low values of physiological dead space, alveolar dead space due to alveoli with high ventilation/perfusion ratio does not appear to be of any critical importance for gas exchange. This is in accordance with the findings of a very small arterial-alveolar P_{CO_2} difference (Nelson et al., 1962 b).

The contribution of the different components to the total alveolar-arterial oxygen tension difference can be shown to correspond to the following gas pressure gradients (Rahn and Farhi, 1962; Rahn and Farhi, 1964): alveolar dead space component to $P_{aCO_2} - P_{ACO_2}$, low ventilation/perfusion component to $P_{aN_2} - P_{AN_2}$ and the anatomic shunt component to approximately $(P_{AO_2} - P_{aO_2}) - (P_{aCO_2} - P_{ACO_2}) - (P_{aN_2} - P_{AN_2}) = P_{cO_2} - P_{aO_2}$ (VI). Although only P_{O_2} differences have been determined in the present investigation (VI), these differences have been calculated from the mean values obtained at 24 hours and 7 days of age and have been collected in Fig. 5, and opposed to typical figures for normal adults in order to demonstrate the peculiarity of gas exchange in the newborn infant.

While lung compliance shows a steady increase during the first 24 hours of life pulmonary resistance appears to be mainly unchanged after the age of 1—2 hours (Table II) averaging 27 cm $H_2O/l/sec$ At 2—35 minutes of life pulmonary resistance averaged 35 ± 20 cm $H_2O/l/sec$ the difference between this value and the value found later is however statistically not significant. The values obtained after 1—2 hours of life are in good agreement with those obtained at corresponding ages by using pneumotachygraph flow recording (Swyer et al 1960 26 cm $H_2O/l/sec$, Polgar and String, 1966 34 cm $H_2O/l/sec$) or calculation of flow rate from volume recording by means of a body plethysmograph (Cook et al. 1957 29 cm $H_2O/l/sec$

Recently Polgar and collaborators succeeded in measuring even the subdivisions of pulmonary resistance airway resistance and lung tissue resistance in the newborn infant. They determined airway resistance by means of the total body plethysmograph technique (DuBois et al. 1956) and lung tissue resistance by the method of Marshall and DuBois (1956) substracting the airway resistance measured plethysmographically from the pulmonary resistance determined by directly plotting the resistive component of intraoesophageal pressure against airflow on an x y oscillograph (Polgar and String 1966) By substracting total pulmonary resistance measured when breathing through a plastic oral airway of known resistance from the pulmonary resistance measured when breathing through the nose even nasal resistance to breathing could be estimated (Polgar and Kong, 1965) this latter was found to be $12\,1 \pm 5\,5$ cm $H_2O/l/sec$ ($n = 5$) or about 42 per cent of the total airway resistance against about 63 per cent in adults However total pulmonary resistance in this series was higher (47 5 cm $H_2O/l/sec$) than values reported by other investigators When measured concurrently total pulmonary resistance was $34\,1 \pm 8.9$ cm $H_2O/l/sec$ and oral breathing airway resistance $25\,4 \pm 6\,4$ cm $H_2O/l/sec$, yielding an average lung tissue resistance of $8\,7 \pm 6$ cm $H_2O/l/sec$ (Polgar and String, 1966) this corresponds to approximately 40 per cent of mean pulmonary resistance corrected for nasal resistance. Though the error involved in this type of study in the newborn infant is larger than in the adult, these results should indicate that total mean opposing resistive forces in relation to minute ventilation are lower in the newborn infant than in the adult (Polgar 1967) This should mainly be due to lower nasal resistance while oral airway resistance is similar and tissue resistance somewhat higher in the newborn infant.

LATE ADJUSTMENT OF INTRAPULMONARY GAS EXCHANGE

After the rapid initial adaptative processes only minor changes occur during the remainder of the first week of life

During the subsequent hours of extrauterine life arterial oxygen saturation and oxygen tension continue to rise attaining by five hours of age 96 ± 3 per cent and 74 ± 12 mm Hg respectively During oxygen breathing, P_{aO_2} rises to 555 ± 56 mm Hg corresponding to an alveolar arterial P_{O_2} difference of 124 ± 54 mm Hg and an anatomic shunt of $9\,8 \pm 3\,9$ per cent of cardiac output. As discussed above these changes coincide with an important rise in lung compliance and probably some adjustment in FRC In spite of further small adjustments in the lung s mechanical properties oxygenation of arterial blood does not undergo any further changes of significance and anatomic shunt appears to be mainly unchanged with however a minimum value at 2 days of age ($7\,6 \pm 3\,1$ per cent) Thus even after one week s »acclimatization to extrauterine existence the lung of the newborn infant has not yet attained the same efficiency for oxy

genation of arterial blood as that of the normal adult.

Theoretically decreased arterial oxygen tension can be caused either by alveolar hypoventilation or by mechanisms increasing the alveolar arterial oxygen tension difference Three factors may contribute to the latter (VI) 1) The *diffusion component* which may give rise to a $P_{AO_2} - P_{cO_2}$ difference in the presence of impaired diffusion, but in the normal subject only under conditions of hypoxic ambient air 2) the *distribution component* including both alveoli receiving an excess of perfusion (low ventilation/ perfusion ratio) and those receiving an excess of ventilation (high ventilation/perfusion ratio, i.e large *alveolar* dead space) and 3) the *shunt component* due to anatomic shunt, i e shunting of venous blood into the post pulmonary circulation thus establishing a $P_{cO_2} - P_{aO_2}$ difference

Alveolar oxygen and carbon dioxide tensions (VI) exclude alveolar hypoventilation at least from the age of 24 hours but similar alveolar gas tensions have been reported already at the age of 4 hours (Prod'hom et al. 1964) and are at least in the normal infant, probably present even earlier as judged from arterial P_{CO_2} (IV)

In view of the magnitude of D_{LCO} and the low $P_{AO_2} - P_{cO_2}$ difference observed in the present study the diffusion component does not appear to contribute substantially to the $P_{AO_2} - P_{aO_2}$ difference at least during breathing of air and hyperoxic inspiratory gases

Thus the alveolar-arterial P_{O_2} difference of 31 and 30 mm Hg during air breathing at 24 hours and 7 days corresponding to a total venous admixture of on the average 20.9 and 18.4 per cent of the cardiac output ($D = 2.5$ $p < 0.05$) should be due to the effect of shunt and distribution component.

Since anatomic shunt determined during oxygen breathing was found to be 9.3 ± 3.5 and 9.7 ± 4.3 per cent of cardiac output respectively It should account for approximately 43 and 59 per cent of total venous admixture at the age of 24 hours and 7 days respectively If one assumes that oxygen breathing does not change significantly neither blood flow through shunt channels nor the arterial-mixed venous O_2 difference (cf V)

These results are conflicting with those from earlier reports (Nelson et al., 1963 b Prod'hom et al 1964) concerning mainly slightly premature infants delivered by cesarean section, in which venous admixture at least after 4 hours of age was considered to be mainly due to true anatomic shunt. The main causes for this discrepancy appear to be methodological differences in measuring P_{O_2} in blood with high oxygen tensions and the difference in gestational age of the infants studied and the type of their delivery (V)

As indicated by the low values of physiological dead space alveolar dead space due to alveoli with high ventilation/perfusion ratio does not appear to be of any critical importance for gas exchange This is in accordance with the findings of a very small arterial alveolar P_{CO_2} difference (Nelson et al 1962 b)

The contribution of the different components to the total alveolar arterial oxygen tension difference can be shown to correspond to the following gas pressure gradients (Rahn and Farhi, 1962, Rahn and Farhi 1964) alveolar dead space component to $P_{aCO_2} - P_{ACO_2}$, low ventilation/perfusion component to $P_{aN_2} - P_{AN_2}$, and the anatomic shunt component to approximately $(P_{AO_2} - P_{aO_2}) - (P_{aCO_2} - P_{ACO_2}) - (P_{aN_2} - P_{AN_2}) = P_{cO_2} - P_{aO_2}$ (VI) Although only P_{O_2} differences have been determined in the present investigation (VI) these differences have been calculated from the mean values obtained at 24 hours and 7 days of age and have been collected in Fig. 5 and opposed to typical figures for normal adults in order to demonstrate the peculiarity of gas exchange in the newborn infant.

While lung compliance shows a steady in crease during the first 24 hours of life pul monary resistance appears to be mainly un changed after the age of 1—2 hours (Table II) averaging 27 cm $H_2O/l/sec$. At 2—35 minutes of life pulmonary resistance averaged 35 ± 20 cm $H_2O/l/sec$ the difference between this value and the value found later is however statistically not significant. The values obtained after 1—2 hours of life are in good agreement with those obtained at corresponding ages by using pneumotachy graph flow recording (Swyer et al. 1960 26 cm $H_2O/l/sec$ Polgar and String, 1966 34 cm $H_2O/l/sec$) or calculation of flow rate from volume recording by means of a body plethysmograph (Cook et al 1957 29 cm $H_2O/l/sec$.

Recently Polgar and collaborators suc ceeded in measuring even the subdivisions of pulmonary resistance airway resistance and lung tissue resistance in the newborn infant. They determined airway resistance by means of the total body plethysmograph tech nique (DuBois et al. 1956) and lung tissue resistance by the method of Marshall and DuBois (1956) substracting the airway resist ance measured plethysmographically from the pulmonary resistance determined by di rectly plotting the resistive component of intraoesophageal pressure against airflow on an x y oscillograph (Polgar and String, 1966) By substracting total pulmonary resistance measured when breathing through a plastic oral airway of known resistance from the pulmonary resistance measured when breath ing through the nose even nasal resistance to breathing could be estimated (Polgar and Kong, 1965) this latter was found to be 12 1 ± 5 5 cm $H_2O/l/sec$ (n = 5) or about 42 per cent of the total airway resistance against about 63 per cent in adults However total pulmonary resistance in this series was higher (47 5 cm $H_2O/l/sec$) than values re ported by other investigators When measured concurrently total pulmonary resistance was 34 1 ± 8.9 cm $H_2O/l/sec$ and oral breathing airway resistance 25 4 ± 6 4 cm $H_2O/l/sec$ yielding an average lung tissue resistance of 8 7 ± 6 cm $H_2O/l/sec$ (Polgar and String, 1966) this corresponds to approximately 40 per cent of mean pulmonary resistance cor rected for nasal resistance Though the error involved in this type of study in the newborn infant is larger than in the adult, these results should indicate that total mean opposing re sistive forces in relation to minute ventilation are lower in the newborn infant than in the adult (Polgar 1967) This should mainly be due to lower nasal resistance while oral air way resistance is similar and tissue resistance somewhat higher in the newborn infant.

LATE ADJUSTMENT OF INTRAPULMONARY GAS EXCHANGE

After the rapid initial adaptative processes only minor changes occur during the remainder of the first week of life.

During the subsequent hours of extraute rine life arterial oxygen saturation and oxy gen tension continue to rise attaining by five hours of age 96 ± 3 per cent and 74 ± 12 mm Hg respectively During oxygen breathing, P_{aO_2} rises to 555 ± 56 mm Hg corresponding to an alveolar arterial P_{O_2} differ ence of 124 ± 54 mm Hg and an anatomic shunt of 9 8 ± 3.9 per cent of cardiac output. As discussed above these changes coincide with an important rise in lung compliance and probably some adjustment in FRC In spite of further small adjustments in the lung s mechanical properties oxygenation of arterial blood does not undergo any further changes of significance and anatomic shunt appears to be mainly unchanged with how ever a minimum value at 2 days of age (7 6 ± 3 1 per cent) Thus even after one week s acclimatization to extrauterine ex istence the lung of the newborn infant has not yet attained the same efficiency for oxy

genation of arterial blood as that of the normal adult.

Theoretically decreased arterial oxygen tension can be caused either by alveolar hypoventilation or by mechanisms increasing the alveolar arterial oxygen tension difference. Three factors may contribute to the latter (VI) 1) The *diffusion component* which may give rise to a $P_{AO_2} - P_{cO_2}$ difference in the presence of impaired diffusion, but in the normal subject only under conditions of hypoxic ambient air 2) the *distribution component* including both alveoli receiving an excess of perfusion (low ventilation/perfusion ratio) and those receiving an excess of ventilation (high ventilation/perfusion ratio, i.e. large *alveolar* dead space) and 3) the *shunt component* due to anatomic shunt, i.e. shunting of venous blood into the post pulmonary circulation thus establishing a $P_{O_2} - P_{aO_2}$ difference.

Alveolar oxygen and carbon dioxide tensions (VI) exclude alveolar hypoventilation at least from the age of 24 hours but similar alveolar gas tensions have been reported already at the age of 4 hours (Prod'hom et al., 1964) and are at least in the normal infant probably present even earlier as judged from arterial P_{CO_2} (IV).

In view of the magnitude of D_{LCO} and the low $P_{AO_2} - P_{O_2}$ difference observed in the present study the *diffusion* component does not appear to contribute substantially to the $P_{AO_2} - P_{aO_2}$ *difference* at least during breathing of air and hyperoxic inspiratory gases.

Thus the alveolar-arterial P_{O_2} difference of 31 and 30 mm Hg during air breathing at 24 hours and 7 days corresponding to a total venous admixture of on the average *20.9* and 18.4 per cent of the cardiac output ($D = 2.5$ $p < 0.05$) should be *due* to the effect of shunt and distribution component.

Since anatomic shunt determined during oxygen breathing was found to be 9.3 ± 3.5 and 9.7 ± 4.3 per cent of cardiac output respectively it should account for approximately 43 and 59 per cent of total venous admixture at the age of 24 hours and 7 days respectively if one assumes that oxygen breathing does not change significantly neither blood flow through shunt channels nor the arterial mixed venous O_2 difference (cf. V).

These results are conflicting with those from earlier reports (Nelson et al. 1963 b Prod'hom et al. 1964) concerning mainly slightly premature infants delivered by caesarean section, in which venous admixture at least after 4 hours of age was considered to be mainly due to true anatomic shunt. The main causes for this discrepancy appear to be methodological differences in measuring P_{O_2} in blood with high oxygen tensions and the difference in gestational age of the infants studied and the type of their delivery (V).

As indicated by the low values of physiological dead space alveolar dead space due to alveoli with high ventilation/perfusion ratio does not appear to be of any critical importance for gas exchange. This is in accordance with the findings of a very small arterial alveolar P_{CO_2} difference (Nelson et al., 1962 b).

The contribution of the different components to the total alveolar arterial oxygen tension difference can be shown to correspond to the following gas pressure gradients (Rahn and Farhi 1962 Rahn and Farhi 1964) alveolar dead space component to $P_{CO_2} - P_{ACO_2}$ low ventilation/perfusion component to $P_{aN_2} - P_{AN_2}$, and the anatomic shunt component to approximately $(P_{AO_2} - P_{aO_2}) - (P_{CO_2} - P_{ACO_2}) - (P_{aN_2} - P_{AN_2}) = P_{cO_2} - P_{O_2}$ (VI). Although only P_{O_2} differences have been determined in the present investigation (VI) these differences have been calculated from the mean values obtained at 24 hours and 7 days of age and have been collected in *Fig. 5* and opposed to typical figures for normal adults in order to demonstrate the peculiarity of gas exchange in the newborn infant.

While lung compliance shows a steady increase during the first 24 hours of life pulmonary resistance appears to be mainly unchanged after the age of 1—2 hours (Table II) averaging 27 cm H_2O/l/sec. At 2—35 *minutes of life pulmonary resistance* averaged 35 ± 20 cm H_2O/l/sec, the difference between this value and the value found later is however statistically not significant. The values obtained after 1—2 hours of life are in good agreement with those obtained at corresponding ages by using pneumotachygraph flow recording (Swyer et al 1960 26 cm H_2O/l/sec Polgar and String, 1966 34 cm H_2O/l/sec) or calculation of flow rate from volume recording by means of a body plethysmograph (Cook et al 1957 29 cm H_2O/l/sec

Recently Polgar and collaborators succeeded in measuring even the subdivisions of pulmonary resistance airway resistance and lung tissue resistance in the newborn infant. They determined airway resistance by means of the total body plethysmograph technique (DuBois et al. 1956) and lung tissue resistance by the method of Marshall and DuBois (1956) substracting the airway resistance measured plethysmographically from the pulmonary resistance determined by directly plotting the resistive component of intraoesophageal pressure against airflow on an x y oscillograph (Polgar and String, 1966) By substracting total pulmonary resistance measured when breathing through a plastic oral airway of known resistance from the pulmonary resistance measured when breathing through the nose, even nasal resistance to breathing could be estimated (Polgar and Kong 1965) *this latter was found to be* $12 1 \pm 5 5$ cm H_2O/l/sec ($n = 5$) or about 42 per cent of the total airway resistance against about 63 per cent in adults However total pulmonary resistance in this series was higher (47.5 cm H_2O/l/sec) than values reported by other investigators When measured concurrently total pulmonary resistance was $34 1 \pm 8.9$ cm H_2O/l/sec and oral breathing airway resistance $25 4 \pm 6 4$ cm H_2O/l/sec *yielding an average lung tissue resistance* of $8 7 \pm 6$ cm H_2O/l/sec (Polgar and String, 1966) this corresponds to approximately 40 per cent of mean pulmonary resistance corrected for nasal resistance. Though the error involved in this type of study in the newborn infant is larger than in the adult, these results should indicate that total mean opposing resistive forces in relation to minute ventilation are lower in the newborn infant than in the adult (Polgar 1967) This should mainly be due to lower *nasal resistance* while *oral* airway resistance is similar and tissue resistance somewhat higher in the newborn infant.

LATE ADJUSTMENT OF INTRAPULMONARY GAS EXCHANGE

After the rapid initial adaptative processes only minor changes occur during the remainder of the first week of life

During the subsequent hours of extrauterine life, arterial oxygen saturation and oxygen tension continue to rise attaining by five hours of age 96 ± 3 per cent and 74 ± 12 mm Hg respectively During oxygen breathing, P_{aO_2} rises to 555 ± 56 mm Hg corresponding to an alveolar arterial P_{O_2} difference of 124 ± 54 mm Hg and an anatomic shunt of $9 8 \pm 3.9$ per cent of cardiac output As discussed above these changes coincide with an important rise in lung compliance and probably some adjustment in FRC In spite of further small adjustments in the lung s mechanical properties oxygenation of *arterial blood does not undergo* any further changes of significance and anatomic shunt appears to be mainly unchanged, with however a *minimum value at 2 days* of age ($7 6 \pm 3 1$ per cent) Thus even after one week s acclimatization to extrauterine existence the *lung of the newborn infant has* not yet attained the same efficiency for oxy

corresponding values of estimated Q was 0.63 and 0.66 at 24 hours and 7 days respectively and thus significantly lower than in adults. Even these figures suggest the presence of an important number of alveoli with low ventilation/perfusion ratio which has been shown to account for part of the total venous admixture. The slight increase in overall V_A/Q between 24 hours and 7 days, though statistically not significant, is in accordance with the finding of a decreasing contribution of the distribution component to total venous admixture during the same age period.

ACID-BASE BALANCE

Composition of cord blood during delivery reflects the more or less pronounced disturbance of the functional relationship between mother and fetus during labour and delivery (James 1965) but does not reflect the normal basal condition in utero. Great interindividual differences in the degree of this disturbance even in the course of the normal delivery obviously account for the wide variation of normal P_{O_2}, P_{CO_2}, pH and bicarbonate values reported in both arterial and venous cord blood (cf. Wulf 1967, IV).

There are no figures available for human fetal blood gas and acid-base relations in the undisturbed basal state in utero. It is however well established (cf. IV) that there is maternal respiratory alkalosis during pregnancy secondary to hormone induced hyperventilation, compensated by hypobasemia which results in unchanged or slightly elevated pH. Hyperventilation corresponds to a P_{aCO_2} of about 30—32 mm Hg and a decrease of standard bicarbonate by about 3 meq/l while P_{O_2} is within the normal range (IV).

With respect to the structure of the human placenta and its functional properties (Metcalfe 1967, Wulf 1967) it seems reasonable to assume a P_{CO_2} for umbilical venous blood during intrauterine steady state conditions only a few mm Hg higher than the maternal arterial P_{CO_2} since the composition of the intervillous capillary space blood must lie between that of maternal arterial and uterine venous blood and P_{CO_2} is likely to be lower than the 38 mm Hg found in umbilical venous blood at the end of the delivery process (IV).

This value is admittedly somewhat lower than the umbilical venous P_{CO_2} values reported in most of the previous studies (cf. Wulf 1967) but it is in perfect agreement with that found by Engström et al. (1966) which is probably due to the fact that in these two studies analyses were performed shortly after blood sampling.

On the other hand an important P_{O_2} gradient must be expected through the placental barrier because of the oxygen consumption of the placenta itself which must be significant at least near term (Dawes 1965) and veno-arterial shunts which seem to be present on both sides of the barrier (Metcalfe 1967, Wulf 1967). According to Dawes (1965) reasonable figures would be 20 to 30 mm Hg for umbilical arterial and 40 to 50 mm Hg for umbilical venous P_{O_2} which would cover the observations on different species and also the upper limits of the figures reported for human cord blood during or immediately after delivery.

While it thus appears that the fetus in utero is living in a state of slight hypocapnea and decreased oxygen tension according to adult standards and as judged from umbilical venous pH at birth and from resting maternal lactate values (Derom, 1964) if ever only in a slightly acidotic environment, the delivery process induces more or less pronounced respiratory and metabolic acidosis due to CO_2 retention and accumulation of fixed acids along with hypoxemia which increase postnatally until a maximum is reached at about 1—2 minutes (Engström et al. 1966, IV). Subsequent recovery from the acidotic state at birth is primarily achieved by pulmonary elimination of carbon dioxide while recession of true metabolic acidosis as judged from lactate concentrations will take several hours up to one day (IV, Fig. 6). This adjustment

The arterial alveolar P_{N_2} difference cal culated on the basis of shunt estimations is in good agreement with the urinary-alveolar P_{N_2} difference actually determined in the newborn infant (Rahn and Farhi 1964) Since nitrogen is an inert gas its pressure in the urine is equal to that in the tissues and in the arterial and venous blood (cf Rahn and Farhi 1964)

It is noteworthy that the contribution of the low ventilation/perfusion distribution component decreased from about 57 per cent of total venous admixture at 24 hours to about 40 per cent at 7 days ($p < 0.01$) This finding is in perfect agreement with the ob servation of a decreasing urinary alveolar P_{N_2} difference in the newborn infant during the first 5 days of life (Rahn and Farhi 1964)

A further reduction of the distribution component appears to occur during the fol lowing months of life In the infant of some months of age the distribution component has been estimated to account for only about 10 per cent of total venous admixture (Riegel 1967)

Calculation of cardiac output from oxygen uptake and an arterial mixed venous oxygen difference of 3.5 ml/100 ml yields values in surprisingly good agreement with figures ob tained by direct measurement (Gessner et al 1965 Burnard et al 1966 Arcilla et al 1967) The overall pulmonary ventilation perfusion ratio calculated from V_A and the

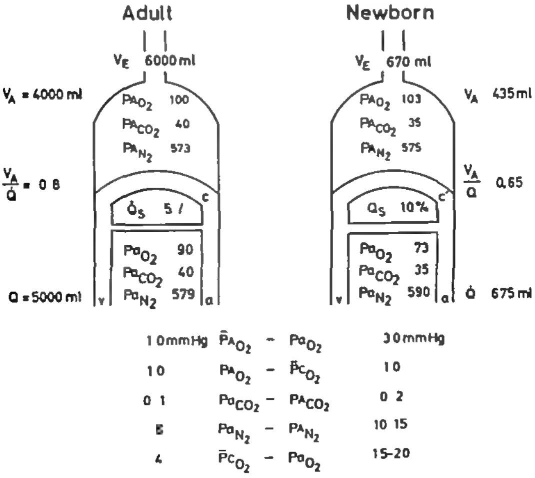

FIG 5 Comparison between typical figures of respiratory exchange in the adult and the newborn infant after the first day of life (VI)

corresponding values of estimated Q was 0.63 and 0.66 at 24 hours and 7 days respectively and thus significantly lower than in adults. Even these figures suggest the presence of an important number of alveoli with low ventilation/perfusion ratio which has been shown to account for part of the total venous admixture. The slight increase in overall V_A/Q between 24 hours and 7 days, though statistically not significant, is an accordance with the finding of a decreasing contribution of the distribution component to total venous admixture during the same age period.

ACID-BASE BALANCE

Composition of cord blood during delivery reflects the more or less pronounced disturbance of the functional relationship between mother and fetus during labour and delivery (James, 1965) but does not reflect the normal basal condition in utero. Great inter individual differences in the degree of this disturbance even in the course of the normal delivery obviously account for the wide variation of normal P_{O_2}, P_{CO_2}, pH and bicarbonate values reported in both arterial and venous cord blood (cf. Wulf 1967, IV).

There are no figures available for human fetal blood gas and acid base relations in the undisturbed basal state in utero. It is however well established (cf. IV) that there is maternal respiratory alkalosis during pregnancy secondary to hormone induced hyperventilation, compensated by hypobasemia which results in unchanged or slightly elevated pH. Hyperventilation corresponds to a P_aCO_2 of about 30—32 mm Hg and a decrease of standard bicarbonate by about 3 meq/l while P_{O_2} is within the normal range (IV).

With respect to the structure of the human placenta and its functional properties (Metcalfe, 1967, Wulf 1967) it seems reasonable to assume a P_{CO_2} for umbilical venous blood during intrauterine steady state conditions only a few mm Hg higher than the maternal arterial P_{CO_2} since the composition of the intervillous capillary space blood must lie between that of maternal arterial and uterine venous blood and P_{CO_2} is likely to be lower than the 38 mm Hg found in umbilical venous blood at the end of the delivery process (IV).

This value is admittedly somewhat lower than the umbilical venous P_{CO_2} values reported in most of the previous studies (cf. Wulf 1967) but it is in perfect agreement with that found by Engström et al. (1966) which is probably due to the fact that in these two studies analyses were performed shortly after blood sampling.

On the other hand an important P_{O_2} gradient must be expected through the placental barrier because of the oxygen consumption of the placenta itself which must be significant at least near term (Dawes 1965) and veno-arterial shunts which seem to be present on both sides of the barrier (Metcalfe 1967, Wulf 1967). FIG 8 *Mean and standard deviation of arterial lactic acid concentration at different ages during the first week of life (IV) Symbols as in Fig. 2.*

leads at 24 hours of life to a pattern of acid base status very similar to that of the mother prior to labour i.e a hypocapnea corresponding to a P_{aCO_2} of about 33 mm Hg a hypobasemia corresponding to a standard bicarbonate concentration of about 20 meq/l and a bicarbonate ion concentration of about 19 meq/l and with a pH slightly beneath 7 4 During the further course of the first week P_{aCO_2} increases towards normal adult standards paralleled by an increase in bicarbonate concentration with mainly unchanged lactate levels (Fig 6)

The behavior of P_{CO_2} bicarbonate and lactate suggests that in the normal newborn infant after the age of 24 hours there is if any only insignificant »true metabolic acidosis» i e accumulation of fixed acids In accordance with conditions in the pregnant woman it rather appears that after the age of 24 hours hyperventilation is the primary change which is counterbalanced by a secondary hypobasemia. The cause for this hyperventilation in relation to the metabolic rate is not obvious It may be due to a »presetting of the infant's respiratory center to values to which it had probably been exposed in utero or to a sensibilization of the respiratory center by similar mechanisms as those acting in adult man during altitude acclimatization. Carbon dioxide sensitivity curves in the newborn actually show a similar decrease of carbon dioxide stimulation threshold (Avery et al 1963) as in pregnant women and in altitude adapted subjects (Kellogg, 1963) during their altitude sojourn as well as after return to sea level Though subjected to great interindividual variations the main part of reduction of the increased ventilation after return from altitude to sea level appears to occur on the average during the period of approximately one week (cf IV) which agrees quite well with the observed changes in the newborn infant.

There is evidence that the normal P_{aO_2} in resting subjects breathing air at sea level is low enough to constitute a mild ventilatory stimulation, but becomes effective only when the individual is sensitized to lower P_{aCO_2} (Kellogg 1963) Since there is only a weak, yet statistically significant, correlation between P_{aCO_2} and P_{aO_2} during the first week of life it is however improbable that a chemoreceptor drive plays a major role in the origin of neonatal hyperventilation.

SUMMARY

During gestation the placenta subserves the external respiration of the fetus as well as its metabolism. With the initiation of extra-uterine life the placental circulation is eliminated and the fetus emerges from a watery environment into air. This implies the establishment of a new autonomic function, that of pulmonary respiration, which process is intimately linked to a profound readjustment of the circulation.

The present series of investigations has been performed to elucidate certain of the processes involved in pulmonary gas exchange and to evaluate its efficiency compared to adult standards during the period of adjustment to extrauterine life. Though the most important and rapid changes in this adaptative process occur during the first seconds and minutes of extrauterine life they continue far beyond this period. Observations have therefore been extended until the end of the neonatal period defined as the first week of life; this has been considered particularly important as information as to the later period of this adjustment is scarce or lacking. Emphasis is laid on development of function.

Because of the significant morbidity and mortality of the newborn infant in disorders of respiration all investigations throwing more light on the normal respiratory mechanisms and their alterations in disease have important practical implications by improving diagnostic possibilities and facilitating objective evaluation of therapeutic measures.

A total of 172 healthy fullterm infants born after an uneventful pregnancy of normal length and uncomplicated vertex delivery are the subjects of the different studies.

The size of the subjects to be studied and the lack of cooperation posed special methodological problems. Suitable procedures and methods permitting reproducible and valid measurements have been developed or adapted for the study of mechanics of breathing, functional residual capacity, pulmonary ventilation, diffusing capacity and gas exchange. Since capillary P_{O_2} does not accurately reflect arterial P_{O_2} a safe procedure permitting arterial blood sampling without disturbing steady state conditions had to be developed.

The onset of respiration and initial aeration of the lungs is characterized by the generation of very high resistive forces, probably mainly due to high surface tension. Subsequently lung compliance increases while lung resistance and inspiratory work decrease, the speed of these changes being highest in the beginning and slowing down subsequently.

Within one hour after delivery the functional residual capacity amounts to 40—80 ml and shows a relation to lung compliance similar to that later in life. Changes after 24 hours of life are insignificant.

There is hypoxemia, CO_2 retention and accumulation of fixed acids, i.e. respiratory and metabolic acidosis at birth. The respira

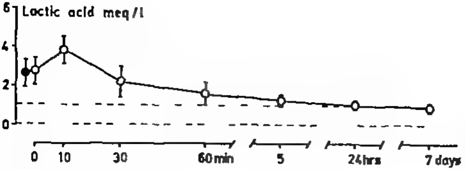

FIG 6. *Mean and standard deviation of arterial lactic acid concentration at different ages during the first week of life (IV) Symbols as in Fig. 2.*

leads at 24 hours of life to a pattern of acid base status very similar to that of the mother prior to labour i.e. a hypocapnea corresponding to a P_{aCO_2} of about 33 mm Hg a hypobasemia corresponding to a standard bicarbonate concentration of about 20 meq/l and a bicarbonate ion concentration of about 19 meq/l and with a pH slightly beneath 7.4 During the further course of the first week P_{aCO_2} increases towards normal adult standards paralleled by an increase in bicarbonate concentration with mainly unchanged lactate levels (Fig 6)

The behavior of P_{CO_2} bicarbonate and lactate suggests that in the normal newborn infant after the age of 24 hours there is if any only insignificant »true metabolic acidosis» i.e. accumulation of fixed acids In accordance with conditions in the pregnant woman it rather appears that after the age of 24 hours hyperventilation is the primary change which is counterbalanced by a secondary hypobasemia. The cause for this hyperventilation in relation to the metabolic rate is not obvious It may be due to a »presetting» of the infant's respiratory center to values to which it had probably been exposed in utero or to a sensibilization of the respiratory center by similar mechanisms as those acting in adult man during altitude acclimatization. Carbon dioxide sensitivity curves in the newborn actually show a similar decrease of carbon dioxide stimulation threshold (Avery et al 1963) as in pregnant women, and in altitude adapted subjects (Kellogg, 1963) during their altitude sojourn as well as after return to sea level Though subjected to great interindividual variations the main part of reduction of the increased ventilation after return from altitude to sea level appears to occur on the average during the period of approximately one week (cf IV) which agrees quite well with the observed changes in the newborn infant.

There is evidence that the normal P_{aO_2} in resting subjects breathing air at sea level is low enough to constitute a mild ventilatory stimulation but becomes effective only when the individual is sensitized to lower P_{aCO_2} (Kellogg, 1963) Since there is only a weak, yet statistically significant correlation between P_{aCO_2} and P_{aO_2} during the first week of life it is however improbable that a chemoreceptor drive plays a major role in the origin of neonatal hyperventilation

SUMMARY

During gestation the placenta subserves the external respiration of the fetus as well as its metabolism. With the initiation of extrauterine life the placental circulation is eliminated and the fetus emerges from a watery environment into air. This implies the establishment of a new autonomic function, that of pulmonary respiration, which process is intimately linked to a profound readjustment of the circulation.

The present series of investigations has been performed to elucidate certain of the processes involved in pulmonary gas exchange and to evaluate its efficiency compared to adult standards during the period of adjustment to extrauterine life. Though the most important and rapid changes in this adaptative process occur during the first seconds and minutes of extrauterine life they continue far beyond this period. Observations have therefore been extended until the end of the neonatal period defined as the first week of life; this has been considered particularly important as information as to the later period of this adjustment is scarce or lacking. Emphasis is laid on development of function.

Because of the significant morbidity and mortality of the newborn infant in disorders of respiration all investigations throwing more light on the normal respiratory mechanisms and their alterations in disease have important practical implications by improving diagnostic possibilities and facilitating objective evaluation of therapeutic measures.

A total of 172 healthy fullterm infants born after an uneventful pregnancy of normal length and uncomplicated vertex delivery are the subjects of the different studies.

The size of the subjects to be studied and the lack of cooperation posed special methodological problems. Suitable procedures and methods permitting reproducible and valid measurements have been developed or adapted for the study of mechanics of breathing, functional residual capacity, pulmonary ventilation, diffusing capacity and gas exchange. Since capillary P_{O_2} does not accurately reflect arterial P_{O_2} a safe procedure permitting arterial blood sampling without disturbing steady state conditions had to be developed.

The onset of respiration and initial aeration of the lungs is characterized by the generation of very high resistive forces, probably mainly due to high surface tension. Subsequently lung compliance increases while lung resistance and inspiratory work decrease, the speed of these changes being highest in the beginning and slowing down subsequently.

Within one hour after delivery the functional residual capacity amounts to 40—80 ml and shows a relation to lung compliance similar to that later in life. Changes after 24 hours of life are insignificant.

There is hypoxemia, CO_2 retention and accumulation of fixed acids, i.e. respiratory and metabolic acidosis at birth. The respira

tory component of acidosis is on the average abolished at 30 minutes and metabolic acidosis at 24 hours of life P_{CO_2} attains a minimum of about 33 mm Hg at 24 hours of life and increases slightly to 36 mm Hg at 7 days This hyperventilation appears to be counterbalanced by a corresponding hypobasemia which recedes during the subsequent days following closely the increase of P_{CO_2} This regulation shows a striking similarity with the changes occurring during and after adaptation to altitude

Arterial oxygen tension during air breathing increases within 5 hours to on the average about 73 mmHg, after which time no further significant changes occur Arterial oxygen tension is thus significantly lower than in normal adults

Arterial oxygen tension during oxygen breathing averages 309 mmHg at 55 minutes of life and between 527 and 589 mmHg during the period between 5 hours and 7 days of life corresponding to an anatomic R—L shunt of about 24 and between 7 6 and 10 9 per cent of cardic output respectively

Among the different variables studied in connection with the determination of diffusing capacity during steady state conditions at the age of 24 hours and 7 days only the following variables show a statistically significant change during this period heart rate respiratory rate minute ventilation ($\dot{V}_E$) the alveolar ventilation/carbon dioxide elimination ratio (V_A/V_{CO_2}) the respiratory exchange ratio (R) the dead space/tidal volume ratio (V_D/V_T) the pulmonary diffusing capacity for CO the total venous admixture the anatomic shunt/total venous admixtu ratio

Alveolar ventilation in relation to oxyg consumption physiological dead space relation to tidal volume the pulmonary di fusing capacity for CO in relation to oxyge consumption alveolar ventilation and bo surface area and the alveolar – mean pulm nary end capillary oxygen tension differen are of the same order as in healthy restir adults

The alveolar arterial oxygen tension di ference is in the order of 30 mm Hg an mainly unchanged during the age of 24 hou and 7 days It is thus significantly highe than in healthy adults Both anatomic shu and ventilation/perfusion inequality i.e al veoli with low ventilation/perfusion rati account for this difference After the initi adaptation the contribution from ventila tion/perfusion inequality decreases during th first week of life

In accordance with these findings th overall ventilation/perfusion ratio was esti mated to be on the average about 0 65 wit a slight tendency to increase between 2 hours and 7 days

The changes of most of the variables fol lowed continuously from birth to 7 days ca be expressed as a logarithmic function of ag showing that the adaptative changes procee most rapidly in the initial stage

Even at the age of 7 days the lung of th newly born infant has not yet attained th same efficiency with respect to oxygen ex change as that of the healthy adult

RÉSUMÉ

Durant la gestation, le placenta subvient à la respiration du foetus aussi bien qu'à son métabolisme. C'est avec le début de la vie extra-utérine que la circulation placentaire est supprimée et que le foetus surgit à l'air quittant un milieu aqueux. Ceci implique, d'urgence l'établissement d'une nouvelle fonction autonome celle de la respiration pulmonaire Ce processus est intimement lié à une profonde réadaptation de la circulation.

Les présentes séries de recherches ont eu pour but d'éclaircir quelques-uns des processus mis en jeu dans l'échange gazeux pulmonaire et d'évaluer leur efficacité comparée à la norme chez l'adulte durant la période de l'adaptation à la vie extra-utérine. Bien que les changements les plus rapides et les plus importants de cette adaptation se réalisent pendant les premières secondes et minutes de la vie extra-utérine ils se prolongent au-delà de cette période On a donc continué les observations jusqu'à la fin de la période néonatale la première semaine de vie par définition. On a considéré cela comme d'autant plus important que les informations sur la période tardive de l'adaptation sont rares ou inexistantes. Le point a été mis sur le développement de la fonction respiratoire

Le taux tojours considérable de la mortalité néo-natale est en grande partie attribuable aux difficultés de l'adaptation de l'hématose à la naissance. En améliorant les possibilités de diagnostic et d'évaluation des moyens therapeutiques employés au cours des troubles respiratoires les recherches destinées à éclaircir les mécanismes respiratoires physiologiques et leurs deviations patho-physiologiques au cours de détresse respiratoire ont une importance pratique considérable

Un total de 172 enfants venus à terme et en bonne sante après une grossesse sans histoire d'une longueur habituelle et un accouchement à présentation normale sans complications a servi de sujets aux diverses études.

La taille des sujets à étudier et leur manque de coopération ont posé des problèmes de méthodes particuliers Des procédes et des méthodes appropriés permettant des mesures reproductibles et exactes ont été développés ou adaptés à l'étude de la mécanique respiratoire, de la capacité fonctionnelle résiduelle, de la ventilation pulmonaire de la capacité de diffusion et de l'échange gazeux pulmonaire Enfin, on a du étudier la validite du sang capillarie pour remplacer le sang artériel. Le résultat etant négatif en ce qui concerne P_{O_2}, on a du développer un procédé sans danger permettant de prélever du sang artériel sans troubler les conditions stables

Le début de la respiration et l'aération initiale des poumons sont caracterisés par l'apparition de forces de très haute résistance dues surtout probablement, à la haute tension de surface. Ensuite l'accomodation (compliance) pulmonaire augmente tandis que la résistance pulmonaire et le travail

tory component of acidosis is on the average abolished at 30 minutes and metabolic acidosis at 24 hours of life P_{CO_2} attains a minimum of about 33 mm Hg at 24 hours of life and increases slightly to 36 mm Hg at 7 days This hyperventilation appears to be counterbalanced by a corresponding hypobasemia which recedes during the subsequent days following closely the increase of P_{CO_2} This regulation shows a striking similarity with the changes occurring during and after adaptation to altitude

Arterial oxygen tension during air breathing increases within 5 hours to on the average about 73 mmHg after which time no further significant changes occur Arterial oxygen tension is thus significantly lower than in normal adults

Arterial oxygen tension during oxygen breathing averages 309 mmHg at 55 minutes of life and between 527 and 589 mmHg during the period between 5 hours and 7 days of life corresponding to an anatomic R—L shunt of about 24 and between 7 6 and 10 9 per cent of cardic output respectively

Among the different variables studied in connection with the determination of diffusing capacity during steady state conditions at the age of 24 hours and 7 days only the following variables show a statistically significant change during this period heart rate respiratory rate minute ventilation (V_E) the alveolar ventilation/carbon dioxide elimination ratio (V_A/V_{CO_2}) the respiratory exchange ratio (R) the dead space/tidal volume ratio (V_D/V_T) the pulmonary diffusing capacity for CO the total venous admixture the anatomic shunt/total venous admixture ratio

Alveolar ventilation in relation to oxygen consumption physiological dead space in relation to tidal volume the pulmonary diffusing capacity for CO in relation to oxygen consumption alveolar ventilation and body surface area and the alveolar – mean pulmonary end capillary oxygen tension difference are of the same order as in healthy resting adults

The alveolar arterial oxygen tension difference is in the order of 30 mm Hg and mainly unchanged during the age of 24 hours and 7 days It is thus significantly higher than in healthy adults Both anatomic shunt and ventilation/perfusion inequality i e. alveoli with low ventilation/perfusion ratio account for this difference After the initial adaptation, the contribution from ventilation/perfusion inequality decreases during the first week of life

In accordance with these findings the overall ventilation/perfusion ratio was estimated to be on the average about 0 65 with a slight tendency to increase between 24 hours and 7 days

The changes of most of the variables followed continuously from birth to 7 days can be expressed as a logarithmic function of age showing that the adaptative changes proceed most rapidly in the initial stage.

Even at the age of 7 days the lung of the newly born infant has not yet attained the same efficiency with respect to oxygen exchange as that of the healthy adult.

ZUSAMMENFASSUNG

Während der Schwangerschaft besorgt die Placenta den äusseren Gasaustausch und Stoffwechsel des Feten. Mit dem Übergang vom Leben im Wasser d.h. in utero in unsere Luftatmosphäre bei der Geburt entfällt der Placentarkreislauf. Diese Umstellung setzt das unmittelbare Einsetzen einer neuen autonomen Organfunktion voraus, die der Lungen, zum Zwecke des äusseren Gasaustauschs. Dieser Funktionswandel der Lunge ist eng mit tiefgreifenden Umstellungen und Anpassungen des Kreislaufs verbunden.

Ziel der vorliegenden Untersuchungen war es einige der bei der Entwicklung des pulmonalen Gasaustauschs beteiligten Faktoren und Funktionen klarzulegen und ihre Effektivität während der Anpassungsperiode im Vergleich zum gesunden Erwachsenen zu untersuchen. Obwohl die dringlichsten und raschesten Veränderungen im Verlauf dieses Anpassungsvorgangs während der ersten Sekunden und Minuten des extrauterinen Lebens erfolgen, erstrecken Sie sich weit über diesen Zeitabschnitt hinaus. Die vorliegenden Untersuchungen wurden daher auf die gesamte Neonatalperiode d. h. die erste Lebenswoche ausgedehnt. Dies erschien umso wichtiger als unsere Kenntnisse in Bezug auf den späteren Teil der postnatalen Adaptation spärlich sind bzw. entsprechende Untersuchungsresultate gänzlich fehlen. Besonderes Gewicht wurde auf die Veränderungen der Lungenfunktion während der ersten Lebenswoche gelegt.

Der überwiegende Teil der immer noch hohen und während der letzten Jahrzehnte wenig veränderten Neugeborenensterblichkeit beruht auf Schwierigkeiten in der Ausbildung eines adäquaten pulmonalen Gasaustausches. Durch Verbesserung der diagnostischen Möglichkeiten und der Grundlagen zur Beurteilung therapeutischer Massnahmen haben alle Untersuchungen, die zu verbesserter Einsicht in das physiologische und pathophysiologische Geschehen bei der normalen und gestörten Anpassung der Lungenatmung führen, unmittelbare praktische Bedeutung.

Im Ganzen wurden 172 gesunde Kinder untersucht, die nach unauffälliger Schwangerschaft von normaler Dauer und nach unkomplizierter vaginaler Entbindung geboren worden waren. Der klinische Verlauf während der ersten Lebenswoche war bei allen Kindern unauffällig.

Die Grösse der Probanden und das Fehlen jeglicher Möglichkeit zur Mitarbeit in dieser Altersgruppe stellen besondere methodologische Probleme. Brauchbare Verfahren und Methoden mit ausreichender Reproduzierbarkeit und Validität wurden zum Studium von Lungenmechanik, funktioneller Residualkapazität, Lungenventilation, Diffusionskapazität und intrapulmonalem Gasaustausch entwickelt, oder fur die besonderen Verhältnisse modifiziert. Da Kapillärblut kein zuverlässiger Ersatz für arterielles Blut zum Studium der Atemgase insbesondere in Bezug

inspiratoire diminuent la vitesse de ces changements étant tres élevee au début et diminuant ensuite

Une heure après la naissance la capacité fonctionnelle residuelle atteint de 40 à 80 ml et presente un rapport avec la compliance pulmonaire semblable à ce qu il sera plus tard dans la vie. Apres 24 heures les changements sont insignifiants

A la naissance il y a hypoxemie rétention de CO_2 et accumulation d acides fixes c est à-dire acidose respiratoire et métabolique La composante respiratoire d acidose est abolie à 30 minutes en moyenne et l acidose métabolique à 24 heures Le P_{CO_2} atteint un taux minimal d environ 33 mm Hg à 24 heures et augmente legèrement jusqu à 36 mm Hg à 7 jours Cette hyperventilation semble être compensee par une hypobasemie correspondante qui diminue par la suite en suivant de près l augmentation de P_{CO_2} Cette régulation présente une analogie frappante avec les changements survenant durant et apres l adaptation à l altitude

La tension de l oxygène arteriel augmente rapidement jusqu à atteindre la moyenne de 73 mm Hg, à l âge de 5 heures Ensuite aucun autre changement de quelque signification n intervient. Elle est donc significativement plus basse que chez l adulte normal

A l âge de 55 minutes le shunt veino-artériel vrai (anatomique) représente environ 24 % du debit cardiaque De 5 heures jusqu à l âge de 7 jours il varie entre 8 et 11 % Cette reduction survenant au cours des premières heures de la vie correspond vraisemblablement à la forte diminution ou suppression des shunts veino-artériels au niveau des communications foetales

Parmi les différentes variables étudiées lors de la mesure de la capacité de diffusion, sous »steady state à l âge de 24 heures et de 7 jours seules les variables suivantes montrent un changement statistiquement significatif pendant cette période , frequence cardiaque frequence respiratoire, ventilation pulmonaire (V_E) quotient respiratoire (R) rapport entre espace mort et volume courant (V_D/V_T) rapport entre ventilation alvéolaire et élimination de CO_2 ($\dot{V}_A/\dot{V}_{CO_2}$) capacité pulmonaire de diffusion pour CO rapport entre shunt veino-artériel vrai (anatomique) et shunt veino-artériel total (contamination veineuse) (voir Tableau IV)

La ventilation alvéolaire par rapport à la consommation d oxygène $\dot{V}_A/\dot{V}_{O_2}$, ainsi que la capacité pulmonaire de diffusion pour CO par rapport à la consommation d oxygène, et par m² de surface corporelle et le $\bar{P}_{AO_2} - P_{cO_2}$ sont du même ordre que chez l adulte normal au repos

La difference de tension d oxygène alveolo-arteriel ($\bar{P}_{AO_2} - P_{aO_2}$) est de l ordre de 30 mm Hg, et reste à peu près inchangée entre 24 heures et 7 jours Elle est ainsi significativement plus élevée que chez l adulte normal Elle est due à parts approximativement egales à un shunt veino-artériel anatomique et à une inégalité du rapport ventilation/perfusion (contribution venant des alveoles avec rapport ventilation/perfusion diminué) Après l adaptation initiale l importance de la contamination veineuse due à l inégalité ventilation/perfusion par rapport au shunt veino-artériel total diminue pendant la première semaine de vie

En accord avec ces résultats on a évalué le rapport ventilation/perfusion total à 0 65 en moyenne avec une légere tendance à augmenter pendant la période d observation.

Les changements de la plupart des variables suivis d une manière continue de la naissance à 7 jours peuvent être exprimés par des fonctions logarithmiques de l âge montrant que les changements adaptatifs se déroulent le plus rapidement au stade initial

Même à l âge de 7 jours le poumon du nouveau-né n a pas encore atteint la même efficacite quant à l échange d oxygène que celui de l adulte normal.

ZUSAMMENFASSUNG

Während der Schwangerschaft besorgt die Placenta den äusseren Gasaustausch und Stoffwechsel des Feten. Mit dem Übergang vom Leben im Wasser d.h. in utero in unsere Luftatmosphäre bei der Geburt entfällt der Placentarkreislauf. Diese Umstellung setzt das unmittelbare Einsetzen einer neuen autonomen Organfunktion voraus, die der Lungen, zum Zwecke des äusseren Gasaustauschs. Dieser Funktionswandel der Lunge ist eng mit tiefgreifenden Umstellungen und Anpassungen des Kreislaufs verbunden.

Ziel der vorliegenden Untersuchungen war es einige der bei der Entwicklung des pulmonalen Gasaustauschs beteiligten Faktoren und Funktionen klarzulegen und ihre Effektivität während der Anpassungsperiode im Vergleich zum gesunden Erwachsenen zu untersuchen. Obwohl die dringlichsten und raschesten Veränderungen im Verlauf dieses Anpassungsvorgangs während der ersten Sekunden und Minuten des extrauterinen Lebens erfolgen, erstrecken Sie sich weit über diesen Zeitabschnitt hinaus. Die vorliegenden Untersuchungen wurden daher auf die gesamte Neonatalperiode, d. h. die erste Lebenswoche, ausgedehnt. Dies erschien umso wichtiger als unsere Kenntnisse in Bezug auf den späteren Teil der postnatalen Adaptation spärlich sind bzw. entsprechende Untersuchungsresultate gänzlich fehlen. Besonderes Gewicht wurde auf die Veränderungen der Lungenfunktion während der ersten Lebenswoche gelegt.

Der überwiegende Teil der immer noch hohen und während der letzten Jahrzehnte wenig veränderten Neugeborenensterblichkeit beruht auf Schwierigkeiten in der Ausbildung eines adäquaten pulmonalen Gasaustausches. Durch Verbesserung der diagnostischen Möglichkeiten und der Grundlagen zur Beurteilung therapeutischer Massnahmen haben alle Untersuchungen, die zu verbesserter Einsicht in das physiologische und pathophysiologische Geschehen bei der normalen und gestörten Anpassung der Lungenatmung führen, unmittelbare praktische Bedeutung.

Im Ganzen wurden 172 gesunde Kinder untersucht, die nach unauffälliger Schwangerschaft von normaler Dauer und nach unkomplizierter vaginaler Entbindung geboren worden waren. Der klinische Verlauf während der ersten Lebenswoche war bei allen Kindern unauffällig.

Die Grösse der Probanden und das Fehlen jeglicher Möglichkeit zur Mitarbeit in dieser Altersgruppe stellen besondere methodologische Probleme. Brauchbare Verfahren und Methoden mit ausreichender Reproduzierbarkeit und Validität wurden zum Studium von Lungenmechanik, funktioneller Residualkapazität, Lungenventilation, Diffusionskapazität und intrapulmonalem Gasaustausch entwickelt, oder für die besonderen Verhältnisse modifiziert. Da Kapillärblut kein zuverlässiger Ersatz für arterielles Blut zum Studium der Atemgase insbesondere in Bezug

auf P_{O_2} ist, musste ein risikofreies Verfahren zur Gewinnung von arteriellem Blut ohne Storung der steady state Bedingungen ent wickelt bzw angepasst werden.

Beim Einsetzen der Atmung und der ini tialen Belüftung der Lunge kommt es zum Auftreten von hohen Widerstandskraften denen wahrscheinlich hauptsachlich hohe Oberflächenspannungen zugrunde liegen Im weiteren Verlauf nimmt die Lungencompli ance zu wahrend der Lungenwiderstand und die inspiratorische Atemarbeit abnehmen Diese Veranderungen erfolgen am schnellsten im Anfang und nehmen allmahlich ab

Innerhalb von 60 Minuten nach der Geburt betragt die funktionelle Residualkapacitat 40—80 ml Die spezifische Lungencompliance (C_L/FRC) steigt wahrend der ersten 24 Stunden und erreicht Werte die mit denen des gesunden Erwachsenen identisch sind

Bei der Geburt hat des Neugeborene eine Hypoxamie CO_2-Retention und Anhäufung fixer Sauren d h eine respiratorische und metabolische Acidose Die respiratorische Komponente ist im Durchschnitt 30 Minuten nach Geburt und die metabolische Acidose im Alter von 24 Stunden ausgeglichen. P_{aCO_2} erreicht im Alter von 24 Stunden mit 33 mm Hg ein Minimum und steigt dann allmählich auf 36 mm Hg am 8 Lebenstag an Diese Hyperventilation scheint durch eine ent sprechende sekundare Hypobasamie kompensiert zu werden die im Lauf der ersten Lebenswoche zurückgeht und dabei eng dem Anstieg des P_{CO_2} folgt. Diese Anpassung zeigt eine auffällige Ahnlichkeit mit den Veranderungen, die während und nach Höhenanpassung beim Erwachsenen beobach tet werden können

Die arterielle Sauerstoffspannung steigt in nerhalb von 5 Stunden auf im Durchsmitt 73 mm Hg an und zeigt danach während der ersten Lebenswoche keine signifikanten Ver änderungen P_{aO_2} ist demnach signifikant niedriger als beim gesunden Erwachsenen.

Die Kurzschlussblutmenge auf Grund von anatomischen Rechts Links-Shunts betragt 55 Minuten nach der Geburt im Durchschnitt ca 24 % des Minutenvolumens sinkt inner halb der ersten 5 Stunden auf knapp 10 % und zeigt wahrend des Restes der ersten Lebenswoche nur geringfugige Veranderungen Ursache der deutlichen Abnahme zwischen 55 Minuten und 5 Stunden durfte das Aufhören oder zumindesten eine deut liche Verminderung von Rechts Links Shunts durch fetale Kreislaufverbindungen (Foramen ovale Ductus arteriosus Botalli) sein.

Von den verschiedenen Variablen die im Zusammenhang mit der Diffusionskapazität der Lungen unter steady state-Bedingungen im Alter von 24 Stunden und 7 Tagen bestimmt wurden zeigen nur die folgenden eine statistisch signifikante Veranderung im Verlauf dieser Periode Herzfrequenz, respiratorischer Quotient (R) und Verhältnis anatomischer Shunt/gesamte venose Kurz schlussdurchblutung einen Anstieg Atemfrequenz, Minutenventilation (V_E) Verhält nis alveoläre Ventilation/CO_2-Ausscheidung (V_A/V_{CO_2}) Verhaltnis physiologischer Tot raum/Atemzugvolumen (V_D/V_T) Diffusionskapazität für CO sowie die gesamte venose Kurzschlussdurchblutung eine Abnahme (siehe Tabelle IV)

Die alveolare Ventilation im Verhaltnis zum Sauerstoffverbrauch (V_A/V_{O_2}) der physiologische Totraum im Verhältnis zum Atemzugvolumen (V_D/V_T) die Diffusions kapazität für CO im Verhältnis zum Sauer stoffverbrauch, zur alveolären Ventilation und zur Körperoberfläche sowie P_{AO_2} — P_{cO_2} sind in derselben Grössenordnung wie beim gesunden Erwachsenen unter Ruhebedingungen

Die alveolo-arterielle Sauerstoffdruckdiffe renz bei Luftatmung liegt in der Grössenord nung von 30 mm Hg und ändert sich kaum vom Ende des ersten Lebenstages bis zum Ende der ersten Woche. Sie ist damit deut lich höher als beim gesunden Erwachsene

Anatomischer Rechts-Links Shunt und venöse Beimischung von Alveolen mit niedrigem Ventilations/Perfusions Verhältnis scheinen in nahezu gleichem Ausmass zu dieser Differenz beizutragen. Der Anteil auf Grund ungleichen Ventilations/Perfusions Verhältnisses nimmt im Lauf der ersten Lebenswoche ab

In Übereinstimmung mit diesen Ergebnissen ergab sich für das Gesamt Ventilations/Perfusions-Verhaltnis ein Durchschnittswert von 0.65 mit einer geringen Steigerungstendenz während der ersten Lebenswoche.

Die Veränderung der meisten der von der Geburt bis zum achten Lebenstag systematisch untersuchten Variabeln kann als logarithmische Funktion des Alters ausgedruckt werden (Tabelle III) Dies zeigt, dass die Anpassungsvorgänge am raschesten im Initialstadium erfolgen.

Selbst im Alter von 7 Tagen hat die Neugeborenenlunge in Hinsicht auf den pulmonalen Sauerstoffaustausch noch nicht die gleiche Effektivität erreicht wie die des Erwachsenen.

auf P_{O_2} ist musste ein risikofreies Verfahren zur Gewinnung von arteriellem Blut ohne Störung der steady state Bedingungen ent wickelt bzw angepasst werden.

Beim Einsetzen der Atmung und der ini tialen Belüftung der Lunge kommt es zum Auftreten von hohen Widerstandskraften, denen wahrscheinlich hauptsachlich hohe Oberflächenspannungen zugrunde liegen. Im weiteren Verlauf nimmt die Lungencompli ance zu wahrend der Lungenwiderstand und die inspiratorische Atemarbeit abnehmen. Diese Veranderungen erfolgen am schnellsten im Anfang und nehmen allmählich ab

Innerhalb von 60 Minuten nach der Geburt betragt die funktionelle Residualkapacität 40—80 ml. Die spezifische Lungencompliance (C_L/FRC) steigt wahrend der ersten 24 Stunden und erreicht Werte die mit denen des gesunden Erwachsenen identisch sind.

Bei der Geburt hat des Neugeborene eine Hypoxamie CO_2-Retention und Anhaufung fixer Sauren d h eine respiratorische und metabolische Acidose Die respiratorische Komponente ist im Durchschnitt 30 Minuten nach Geburt und die metabolische Acidose im Alter von 24 Stunden ausgeglichen P_{aCO_2} erreicht im Alter von 24 Stunden mit 33 mm Hg ein Minimum und steigt dann allmahlich auf 36 mm Hg am 8 Lebenstag an Diese Hyperventilation scheint durch eine ent sprechende sekundäre Hypobasamie kom pensiert zu werden die im Lauf der ersten Lebenswoche zuruckgeht und dabei eng dem Anstieg des P_{CO_2} folgt Diese Anpassung zeigt eine auffällige Ahnlichkeit mit den Veränderungen die wahrend und nach Höhenanpassung beim Erwachsenen beobach tet werden können.

Die arterielle Sauerstoffspannung steigt in nerhalb von 5 Stunden auf im Durchsnitt 73 mm Hg an und zeigt danach während der ersten Lebenswoche keine signifikanten Ver änderungen P_{aO_2} ist demnach signifikant niedriger als beim gesunden Erwachsenen.

Die Kurzschlussblutmenge auf Grund von anatomischen Rechts Links Shunts beträgt 55 Minuten nach der Geburt im Durchschnitt ca 24 % des Minutenvolumens sinkt inner halb der ersten 5 Stunden auf knapp 10 % und zeigt wahrend des Restes der ersten Lebenswoche nur geringfügige Veränderun gen Ursache der deutlichen Abnahme zwischen 55 Minuten und 5 Stunden dürfte das Aufhoren oder zumindesten eine deut liche Verminderung von Rechts Links Shunts durch fetale Kreislaufverbindungen (Foramen ovale Ductus arteriosus Botalli) sein.

Von den verschiedenen Variablen die im Zusammenhang mit der Diffusionskapazität der Lungen unter steady state Bedingungen im Alter von 24 Stunden und 7 Tagen be stimmt wurden zeigen nur die folgenden eine statistisch signifikante Veranderung im Verlauf dieser Periode Herzfrequenz, res piratorischer Quotient (R) und Verhältnis anatomischer Shunt/gesamte venose Kurz schlussdurchblutung einen Anstieg Atem frequenz, Minutenventilation (V_E) Verhält nis alveoläre Ventilation/CO_2-Ausscheidung (V_A/V_{CO_2}) Verhältnis physiologischer Tot raum/Atemzugvolumen (V_D/V_T) Diffusions kapazität für CO sowie die gesamte ve nose Kurzschlussdurchblutung eine Abnahme (siehe Tabelle IV)

Die alveoläre Ventilation im Verhaltnis zum Sauerstoffverbrauch (V_A/V_{O_2}) der physiologische Totraum im Verhältnis zum Atemzugvolumen (V_D/V_T) die Diffusions kapazität fur CO im Verhaltnis zum Sauer stoffverbrauch zur alveolären Ventilation und zur Körperoberfläche sowie P_{AO_2} — P_{cO_2} sind in derselben Grössenordnung wie beim gesunden Erwachsenen unter Ruhebe dingungen.

Die alveolo-arterielle Sauerstoffdruckdiffe renz bei Luftatmung liegt in der Grossenord nung von 30 mm Hg und andert sich kaum vom Ende des ersten Lebenstages bis zum Ende der ersten Woche. Sie ist damit deut lich höher als beim gesunden Erwachsenen.

List of Supplements to Acta Pædiatrica Scandinavica

(A list of earlier supplements can be obtained from Almqvist & Wiksells Boktryckeri AB, Uppsala, S eden without charge)

131. Mellbin, Tore, The Children of Swedish Nomad Lapps. A Study of their Health, Growth and Development. Sw kr 25.— 1962
132. Börjeson, Mats, Overweight Children. Sw kr 25.— 1962
133. Lundström, Rolf, Rubella during Pregnancy. A Follow-up Study of Children Born after an Epidemic of Rubella in Sweden 1951 with Additional Investigations on Prophylaxis and Treatment of Maternal Rubella. Sw kr 25.— 1962
134. Möller, Tage, Shunt Operations in Morbus Caeruleus. Results in 161 Cases and Clinical Follow-up. Sw kr 25.— 1962
135. *I Honour of Curt Gyllenswärd at his Retirement from the Professorship of Paediatrics at Karolinska Institutet, June 30, 1962.* Sw. kr 25.— 1962
136. Bille, Bo, *Migraine in School Children. A study of the incidence and short-term prognosis, and a clinical, psychological and electroencephalographic comparison between children with migraine and matched controls.* Sw. kr 25.— 1962
137. Hansen, A. E., Stewart, R. A., Hughes, G. and Söderhjelm, L., Th Relation of Linoleic Acid to Infant Feeding. A Review Sw kr 25.— 1962
138. Wallgren, Eric Ive Pulmonary and Renal Circulation in Children with Patent Ductus Arteriosus. Pre- and Postoperative Studies of Thirty-four Cases. Sw kr 25.— 1963
139. Westin, Björn, Nyberg, Rune, Miller, James A., Jr. nd Wedenberg, Erik, Hypothermia and Transfusion ith Oxygenated Blood in the Treatment of Asphyxia Neonatorum. Sw kr 30.— 1962
140. *The Proceedings of the Thirteenth Northern Paediatric Congress.* Copenhagen, 1961. Edited by E. Winge Flensborg. Sw. kr 30.— 1963
141. Wase-Hächert, Ole and Danner, Märta, Late Prognosis in Tuberculous Meningitis. A clinical, neurological, ophthalmological, otological, psychological, psychiatric, electroencephalographical, radiological and sociomedical study. Sw kr 25.— 1963
142. Sterner Göran, Adenovirus Infection in Childhood. A epidemiological and clinical survey mong Swedish children. Sw. kr 25.— 1963
143. Lundberg, Åke Paroxysmal Tachycardia in Infancy. A Clinical and Experimental Study. Sw kr 25.— 1963
144. Sterky Göran, Diabetic Schoolchildren. Sw kr 30.— 1963
145. Walsh, S. Zoe Evolution of the Electrocardiogram of Healthy Premature Infants During the First Y ar of Life. Sw kr 20.— 1963
146. *In Honour of Sture Siwe at his Retirement from the Professorship of Paediatrics at the University of Lund, June 30, 1963.* Sw kr 25.— 1963
147. Åstrand, P.-O., Engström, L., Eriksson, B. O., Karlberg, P., Nylander, I., Saltin, B. nd Thorén, C., Girl S immers. With Special Reference to Respiratory and Circulatory Adaptation and Gynaecological and Psychiatric Aspects. Sw. kr 25.— 1963
148. Berven, Hans, The Physical Working Capacity of Healthy Children. Seasonal Variations and Effect of Ultraviolet Irradiation and Vitamin-D Supply. Sw kr 20.— 1963
149. Valaes, Theos, Bilirubin Distribution nd Dynamics of Bilirubin Removal by Exchange Transfusion. S kr 25.— 1963
150. Moe, Peter Johan, Iron Requirements in Infancy. Longitudinal studies of iron requirements during the first year of life. Sw kr. 25.— 1963
151. *Preventive Paediatrics in the Undergraduate Curriculum. Symposium Held ith the Collaboration of the World Health Organization of he X International Congress of Paediatrics. Lisbon, 1962.* Edited by Bo Vahlquist. Sw kr 15.— 1963
152. Hjern, Bo and Nylander, Ingvar. Acute Head Injuries in Children. Traumatology. Therapy and Prognosis. Sw kr 15.— 1964
153. Thorén, Claes, Cardiomyopathy in Friedreich's Ataxia. With Studies of Cardiovascular and Respiratory Function. Sw kr 25.— 1964
154. Hall, Bertil, Mongolism in Newborns. A Clinical and C tic Study. Sw kr 30.— 1964
155. Engström, Inga, Respiratory Studies in Children. XI. of Breathing, Lung Volumes and Ventilatory Capacity in Asthmatic Children from Attack to Symptom-free Status. Sw 25.— 1964
156. *Nils Rosén von Rosenstein and his Textbook on Paediatrics.* Edited by Bo Vahlquist and Arvid Wallgren. Sw kr 25.— 1964
157. Bruns, G., Kaijser, K. and Ockerman, P. A., Glycogenosis I (Lack of Glucose-6-Phosphatase) in Four Siblings. Sw. kr 15.— 1964
158. Arnberg, Douglas, Cortisol in the Newborn Infant. Sw 1965
159. *Proceedings of the Fourteenth Northern Paediatric C Stockholm, 1964.* Edited by Y. Larsson. Sw kr 25.— 1965
160. Öckerman, P. A., Glycogen Storage Disease in Swed 25.— 1965
161. Peltonen, T and Hirvonen, L., Experimental Studies on and Neonatal Circulation. Sw kr 20.— 1965
162. Lundström, Karl Martin, Bone Marrow Cell Proliferation i Health and in Haematological Disease during Childhood. kr 25.— 1966
163. *Newborn Infant Cry.* Edited by John Lind. Sw. kr 30.— 1965
164. Böttiger, Margareta, Studies on Immunization with and Live Poliovirus Vaccines. Sw kr. 20.— 1966
165. Glauser, E. M., Cook, C. D., Harris, G. B. C. and Bate, J. W Bronchiectasis. A Review of 187 Cases in Children with up Pulmonary Function Studies in 58. Sw. kr 20.— 1966
166. *Laaksonen, Anna-Liisa, A Prognostic Study of Juvenile toid Arthritis. Analysis of 544 Cases.* Sw kr 25.— 1966
167. Ivemark, Torben, Listeriosis in Infancy and Childhood. A M rial of 570 Danish Cases. Sw. kr 30.— 1966
168. Trojaborg, W Focal Spike Discharges in Children, Longitudinal Study. Sw. kr 25.— 1966
169. Dahl Mattl, Intracardiac Phonocardiography of the in Children. Sw. kr 30.— 1966
170. Callmer, Margit, Studies on Encopresis. Sw kr 30.— 1966
171. Olding, Lars, Bacterial Infection in Cases of Perinatal Death. A Morphological and bacteriological study based on 264 autopsies. Sw kr 30.— 1966
172. *Festschrift in Memory of Constantin Chevrak.* S kr 25.— 1967
173. Walsh, S. Zoe, The Esophageal Electrocardiogram during the First Week of Life. Sw. kr 15.— 1967
174. Petersson Per Olov, Atrial Septal Defect of Secundum type. A clinical study before and after operation with special reference to haemodynamic function. Sw. kr 25.— 1967
175. Hänninen, Pentti, Vectorcardiographic Studies in Newborn Infants. Sw kr 25.— 1967
176. Berglund, Bo, Studies on Respiratory Syncytial Virus Infection. Sw kr 20.— 1967
177. *Proceedings of the Fifteenth Northern Pediatric Congress.* Bergen, 1967. Sw kr 35.— 1967
178. Sjögren, Irène, Echoencephalography in Paediatric Practice with Special Regard to Measurement of the Ventricular Size. Sw. kr 25.— 1967
179. *Quantitative Studies of the Human Neonatal Circulation.* Edited by Göran Wallgren. Sw kr 25.— 1967
180. Andersen, Hans Jørgen, Clinical Studies on the Antibody Response to *E. Coli* O-Antigens in Infants and Children with Urinary Tract Infection, Using Passive Haemagglutination Technique. Sw kr 20.— 1968
181. Koch, Günter, Lung Function and Acid-Base Balance in the Newborn Infant. Sw kr 20.— 1968
182. Westphal, Otto, Human Growth Hormone. A Methodological and Clinical Study. Sw kr 25.— 1968
183. Robertson, Alex F. and Sprecher, Howard, A Review of Human Placental Lipid Metabolism and Transport. Sw. kr. 25.— 1968

Price Swed. kr 20.—

Printed in Sweden by Almqvist & Wiksells Boktryckeri AB, Uppsala

ACTA PÆDIATRICA SCANDINAVICA

SUPPLEMENT 180 1968

CLINICAL STUDIES ON THE ANTIBODY RESPONSE TO *E COLI* O ANTIGENS IN INFANTS AND CHILDREN WITH URINARY TRACT INFECTION, USING A PASSIVE HAEMAGGLUTINATION TECHNIQUE

BY HANS JÖRGEN ANDERSEN

ALMQVIST & WIKSELL STOCKHOLM SWEDEN
